Because bacterial infections cause significant morbidity and mortality in neutropenic patients, broad-spectrum antibacterial prophylaxis is often used during periods of profound neutropenia with the best data available for levofloxacin. Institutional protocols and resistance patterns drive selection of specific prophylactic agents. Oral prophylaxis regimens are generally discontinued and substituted with intravenous antibacterials with enhanced activity against *Pseudomonas aeruginosa* with the first onset of fever. The use of oral antibiotics among low-risk, neutropenic patients with fever is guided by the use of standardized scoring systems (e.g., MASCC index).

The most common serious infections occurring in neutropenic patients with mucositis are bacteremias due to viridans group streptococci and gram-negative bacilli. Such infections are particularly common during the first several weeks following HSCT, so broad-spectrum antimicrobial prophylaxis is generally given during this time period. The propensity of viridans streptococci to develop resistance to quinolones, and gram-negative bacilli to be resistant to quinolones and β-lactams, means that there is no perfect preventive regimen.

Central venous catheter placement through the skin can lead to blood infection from colonizing gram-positive skin organisms, despite sterile, operative placement of these catheters and antisepsis cleansing procedures.[30] Because gram-positive bacteremias, including those caused by coagulase-negative *Staphylococcus* species, usually are not immediately life threatening, antimicrobials with expected activity against typical gram-positive organisms are not routinely recommended for all febrile patients with a catheter. Indications for empirically adding an anti-Gram-positive antimicrobial (e.g., vancomycin) include evidence of infection at the catheter site and septic shock, The use of antimicrobial-coated bloodstream catheters can be effective in reducing rates of catheter-related bloodstream infections.

Once a gram-positive bacterial infection is identified, vancomycin therapy is often used empirically until the susceptibility profile

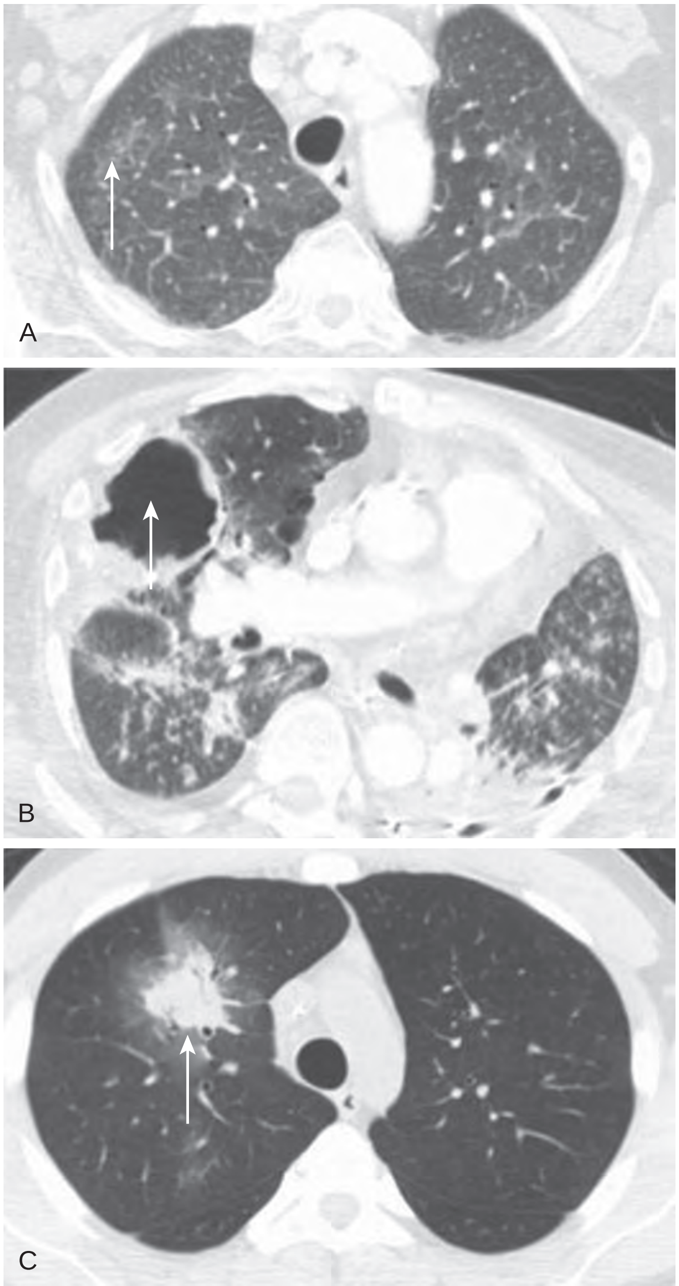

Figure 94.4 COMPUTED TOMOGRAPHY SCAN EXAMPLES OF DIFFERENT PULMONARY INFILTRATES IN IMMUNOCOMPROMISED PATIENTS. (A) Diffuse ground-glass opacities in a patient with *Pneumocystis jirovecii* pneumonia. (B) Cavitary lung lesion in a patient with *Pseudomonas aeruginosa* pneumonia. (C) Lung nodule with halo sign due to *Aspergillus*. For each panel, the *arrow* points to involved pulmonary parenchyma.

is available and targeted therapy can be provided. There are concerns about the efficacy of vancomycin in treating serious *S. aureus* infections because of relative or frank vancomycin resistance and risk of nephrotoxicity in the host. Several alternative therapies to vancomycin should be considered[31] depending on the site of infection and clinical indication, warranting infectious diseases consultation.[32] Similarly, if the patient is known to be colonized with vancomycin-resistant enterococcus and the Gram stain indicates gram-positive organisms in chains, therapy for empiric vancomycin-resistant enterococcus is appropriate until the bacterial identification and susceptibility profile is available, usually with daptomycin or linezolid.

Once a gram-negative infection is identified, empiric therapy that includes *Pseudomonas* coverage is continued until the susceptibility profile is available. In severely neutropenic hosts, serious gram-negative infections are often treated with combination therapy consisting of a β-lactam plus an aminoglycoside depending on the antimicrobial sensitivity pattern and patient comorbidities. However, data demonstrating the superiority of combination therapy over β-lactam monotherapy are lacking.[27] The emergence of extended-spectrum β-lactamase and carbapenemase producing gram-negative bacilli is a particular concern as these pathogens can rapidly evolve into pan-resistant organisms, such as multidrug-resistant *Acinetobacter baumannii* (see box on Treatment of Drug-Resistant Gram-Negative Bacilli). For most infections, the antimicrobial regimen can be tailored to a single agent and continued for 2 weeks after the last positive culture in clinically responding patients. Therapy with a carbapenem resistant to β-lactamase hydrolysis is required if an organism is isolated that is known to have an inducible β-lactamase enzyme (e.g., *Enterobacter*).

For bloodstream infections, repeat blood cultures should be drawn after 2 to 3 days of effective therapy to ensure that sterilization of the bloodstream has been achieved. Persistently positive blood cultures suggest the development of a deep-seated or endovascular site of infection, such as infective endocarditis or suppurative thrombophlebitis. When a bloodstream catheter is proven to be the source of the infection,[30] removal of the catheter may be required for most, but not all, infections. At the end of a 14-day treatment course beyond the last positive culture, the patient should be transitioned to an oral gram-negative prophylaxis regimen if still neutropenic.

Antimicrobial agents with anaerobic activity should be added for neutropenic enterocolitis, enlargement of neck soft tissues during mucositis (Ludwig angina variant), or culture-documented anaerobic infection. Infrequently, tuberculous and nontuberculous mycobacteria are responsible for infections in the bloodstream, catheters, and pulmonary tree. Infections of central catheters or catheter tunnels caused by rapidly growing atypical mycobacterial infections require a high index of suspicion, as well as specific culture media.[34] Organism identification and drug sensitivities may take several weeks. Tuberculous diseases can be empirically treated based on risk factors. For patients without risk factors for tuberculosis, recovery of acid-fast bacilli will prompt therapy for suspected nontuberculous mycobacteria, usually with clarithromycin and either a quinolone or ethambutol until specific susceptibility information is available. Tailored therapy is often continued for a minimum of 3 to 6 months.

Nocardiosis is an uncommon gram-positive bacterial infection caused by over 30 species of aerobic acid-fast actinomycetes in the genus *Nocardia*. The infection has a predisposition to causing disseminated infections involving the CNS and frequently relapses in the setting of intensive immunosuppression, particularly high-dose corticosteroid therapy. Molecular methods used to identify *Nocardia* species have resulted in the reclassification and renaming of many isolates. *Nocardia* isolates that, in the past, were identified as *N. asteroides* complex have now been reclassified to other, or new, species. Some *Nocardia* species (*N. farcinica*) exhibit unique patterns of virulence and variable susceptibility to antibiotics. Trimethoprim-sulfamethoxazole (TMP-SMX) remains the drug of choice, although breakthrough infections especially in the setting of low-dose (TMP-SMX) prophylaxis may occur but often will still respond to treatments with higher-dose TMP-SMX regimens (e.g., 15 mg/kg/day in three to four divided doses) in combination with a second agent (imipenem). Other treatment options may include linezolid, amikacin, amoxicillin-clavulanate, clarithromycin. Nocardiosis in severely immunocompromised patients requires prolonged treatment (6 months) therefore susceptibility testing plays an important role in therapy selection, particularly in patients who cannot tolerate TMP-SMX.

Viruses

Neutropenia per se is not a major risk factor for developing viral infections, but concomitant lymphopenia is common and does predispose to infections with a range of viruses.[35] Respiratory virus infections are

TREATMENT OF DRUG-RESISTANT GRAM-NEGATIVE BACILLI

The widespread use of antibiotic prophylaxis among immunocompromised patients has been associated with the development of antimicrobial drug resistance, which is especially problematic among gram-negative bacilli. Drug-resistant organisms can colonize the GI tract for prolonged periods of time and emerge to cause serious infections during periods of neutropenia or other medical stress (e.g., following admission to the intensive care unit).

- *Pseudomonas aeruginosa* is the paradigm for drug resistance among gram-negative bacilli and can develop pan-resistance to antimicrobials. Serious pseudomonal infections are generally treated with two antimicrobial agents, although convincing data supporting this approach are lacking. Meropenem or ceftolozane-tazobactam (a newer advanced generation cephalosporin combined with a beta-lactamase inhibitor) should be considered as initial therapy in centers where the prevalence of multi-drug resistant (MDR) *P. aeruginosa* exceeds 10%. Carbapenem-resistant strains may be treatable with newer combinations regimens that inhibit serine carbapenemase (e.g., ceftazidime-avibactam, meropenem-vaborbactam or imipenem-cilastatin-relebactam). Metallo-carbapenemase-producing strains of *P. aeruginosa* may be treatable with ceftazidime-avibactam plus aztreonam, or if no response, polymyxin B. Confirmation of the in vitro antibiotic susceptibility is critical for these multidrug-resistant isolates and infectious diseases consultation is strongly recommended.
- Extended-spectrum β-lactamase (ESBL) production among Enterobacterales such as *Escherichia coli* and *Klebsiella pneumoniae* renders these organisms resistant to non-carbapenem β-lactam antibiotics. Treatment is generally with a carbapenem (e.g., meropenem), although tigecycline is sometimes used.
- The presence of a *Klebsiella pneumoniae* carbapenemase (KPC) can occur among species other than *K. pneumoniae* and creates resistance to most β-lactam antibiotics including carbapenems. Antibiotic combinations that include newer carbapenemase inhibitors (e.g., ceftazidime-avibactam, meropenem-vaborbactam, imipenem-cilastatin-relebactam) are preferred over polymyxin B-based combination regimens (e.g., with tigecycline or gentamicin) as polymyxins are less effective and carry a higher risk of nephrotoxicity and neurotoxicity. Plazomicin is a newer semi-synthetic aminoglycoside that may retain activity against Enterobacterales resistant to beta-lactams; but it should not be administered as monotherapy.
- Like *P. aeruginosa, A. baumannii* can develop resistance to all known antimicrobials via a variety of mechanisms. This generally occurs among critically ill patients following prolonged stays in the intensive care unit. Treatment options for MDR and extensively-drug resistant (XDR) strains may include polymyxins, minocycline and sulbactam, a β-lactamase inhibitor that possesses some activity against drug-resistant *Acinetobacter*. Cefiderocol, a novel siderophore cephalosporin that uses iron transport systems in bacteria to accumulate in the periplasmic space of bacteria, has been used successfully to treat XDR strains of *A. baumannii*. The selection of a treatment regimen relies on in vitro susceptibility testing.
- *Stenotrophomonas maltophilia* is an intrinsically MDR gram-negative bacteria (GNB) that is the most common carbapenem-resistant bacteria isolated in patients with hematological malignancies. Infections often begin insidiously as slowly progressing breakthrough pneumonia on carbapenem therapy that leads to bacteremia. Occasionally *S. maltophila* are associated with central venous catheter infections. High-dose trimethoprim-sulfamethoxazole (e.g., 15 mg/kg/day intravenously or orally in divided doses based on trimethoprim component) is the best established therapy but can be problematic to use because of bone marrow-suppressive effects and hypersensitivity reactions. More recent guidelines have recommended use of lower doses of trimethoprim-sulfamethoxazole (8–12 mg/kg/day IV or oral in divided doses) with possible addition of a second agent (minocycline, tigecycline, levofloxacin or cefiderocol).[33] Other regimens that may have some efficacy include minocycline or tigecycline, ceftazidime-avibactam + aztreonam, or cefiderocol.
- *Enterobacter, Serratia*, and *Citrobacter* species can elaborate an AmpC β-lactamase following initiation of β-lactam therapy, which can result in a relapsing infection following an initial response. Thus clinicians treating such infections with penicillins or cephalosporins should closely monitor patients for the emergence of resistance. If resistance does emerge, AmpC-producing organisms can be treated with a carbapenem.
- Patients with MDR gram-negative infections should be cared for in such a manner as to minimize spread of these dangerous organisms to other patients. Compliance with infection control protocols is paramount.
- Knowledge of the local epidemiology and antibiogram are important for preemptive and empiric antibiotic choices, especially against gram-negative rods.
- A carefully designed and executed antibiotic stewardship program could curtail unnecessary antibiotic use, thereby decreasing antibiotic selection pressure with a resulting decrease in bacterial resistance rates.

seasonal, except for parainfluenza. A frequent pathogen with clinical significance is respiratory syncytial virus, although influenza, parainfluenza, adenovirus, enteroviruses, the herpesviruses (including human herpesvirus type 6 [HHV-6]), human metapneumovirus, and rhinovirus also produce diffuse interstitial infiltrates and pneumonitis.[20] HHV-6 and human metapneumovirus are not recovered with the usual tests ordered at the time of bronchoscopy, so a high suspicion for infection is required to order specific polymerase chain reaction (PCR) testing. Documented infection with respiratory syncytial virus (RSV) prompts contact and droplet isolation precautions. Treatment components may include ribavirin (typically orally taken instead of the inhaled version), IVIg, and in some cases, monoclonal antibody therapy. However, proof of efficacy of these treatments remains elusive, and the disease can cause significant morbidity and mortality.[36] Secondary graft failure or diffuse alveolar hemorrhage associated with parainfluenza virus infection has been sporadically reported following transplantation.

Infections with novel coronavirus (e.g., severe acute respiratory syndrome coronavirus 2 [SARS-CoV-2]) requires immediate contact and droplet isolation precautions and ideally antiviral therapy such as remdesivir. The role of dexamethasone or other immunosuppressive agents to reduce inflammation in the lungs is less clear in this population, but it may predispose patients to a higher risk for opportunistic fungal infections including invasive aspergillosis.

Patients with lymphopenia are susceptible to a range of herpes virus family infections. Herpes simplex reactivation infections typically manifest as oral or genital ulcers, although more widespread involvement can occur, and are treated with low doses of acyclovir adjusted for renal function (e.g., 5 mg/kg IV every 8 hours) or oral valacyclovir (1 g bid). Reactivation of VZV can be severe in immunosuppressed persons and is treated with higher doses of acyclovir (e.g., 10 mg/kg IV every 8 hours or oral valacyclovir, 1 g three times a day). Use of acyclovir to prevent reactivation of HSV will also prevent VZV reactivation, although a higher dose (1000 mg daily for VZV vs. 500 mg for HSV) is needed. In the absence of prior acyclovir exposure, acyclovir-resistant HSV is very rare. However, HSV infections that appear or persist through acyclovir prophylaxis should be considered acyclovir resistant until viral sensitivity testing can be performed, and consideration should be given to initiating treatment with foscarnet or cidofovir.[37,38] Reports of acyclovir-resistant varicella are extremely rare. Foscarnet infusions affect calcium homeostasis, so monitoring of ionized calcium and phosphorus levels is required during clinical use of the drug. The major side effect of cidofovir is renal toxicity, which can be reduced to some degree with probenecid and hydration. Clinically significant CMV infection can occur during neutropenia, with DNA PCR based methods used for diagnosis and monitoring response to therapy.

HHV-6 is ubiquitous, and reactivation commonly occurs in patients with significant immunosuppression. However, clinically significant disease due to HHV-6 occurs in only a small percentage of patients who have HHV-6 detected in their blood.[23] HHV-6 infection can manifest as fever or pancytopenia. Other recognized clinical syndromes include pneumonitis and encephalitis. The infection is diagnosed by quantitative PCR, although the exact levels of the virus that indicate clinically significant disease are not known. Detection of the virus in the first 3 weeks following transplantation may be associated with early skin maculopapular rash and acute GVHD, but it can also present without overt clinical symptoms. Prospective large-scale studies are needed to determine the role of HHV-6 infection. HHV-6 has 60% DNA homology with CMV, and treatment of documented infection usually is initiated with induction doses of foscarnet or ganciclovir. Responses to antiviral therapy are not universal, and benefits of foscarnet versus ganciclovir have not been determined.

Cidofovir, when combined with aggressive supportive measures, is considered an adjunct in treatment of BK and adenovirus-associated hemorrhagic cystitis. Cidofovir is recommended for the treatment of disseminated adenovirus infections and is typically administered at 1 mg/kg intravenously 3 times a week with probenecid and saline hydration to reduce nephrotoxicity.

Fungi

Most yeast infections in immunosuppressed patients are caused by *Candida*.[39] Candidal organisms that colonize the mouth and gut proliferate when antibacterial agents suppress the coexisting bacterial flora population. Guidelines for the treatment of candidiasis have been issued.[39] Patients who are clinically stable generally can be treated with fluconazole unless there has been previous azole exposure or mold infection is also a concern. Unstable patients or those who have been receiving an azole are usually treated with an echinocandin. Prevention of candidemia among allogeneic HSCT recipients is generally achieved with fluconazole. However, fluconazole does not have activity against some non-albicans *Candida* species (e.g., *C. glabrata, C. krusei*) and all molds (e.g., *Aspergillus, Fusarium*, the Mucorales species). Among patients colonized with yeast species other than *C. albicans*, and among heavily pretreated patients who may have incubating mold infection, prophylaxis using a mold-active triazole (e.g., posaconazole) or an echinocandin is preferred.[40]

Although less common than *Candida* infections, mold infections in immunocompromised hosts are a significant source of mortality, with aspergillosis being the most common (Fig. 94.5). Because such infections are difficult to diagnose using standard microbiologic techniques, there has been significant interest in developing more effective screening tests. When used regularly, the serum *Aspergillus* galactomannan enzyme-linked immunosorbent assay (ELISA) may allow for earlier diagnosis of invasive aspergillosis in some patients. The test is compromised by difficulties with both false-positive and false-negative results and thus needs to be interpreted as part of the overall clinical picture rather than as a stand-alone diagnostic tool. PCR assays that distinguish common *Aspergillus* species and triazole resistance mechanisms are frequently used in European centers in conjunction with galactomannan, but they are not currently approved in the United States.

The development of a fungal infection in a patient receiving voriconazole should raise concern for mucormycosis, which is the second-most common mold infection in many transplant centers. Mucormycosis can rapidly disseminate through the lungs, sinuses, GI tract, and skin, which is uniformly fatal in patients with hematologic malignancies if not diagnosed early and aggressively treated.[41]

Although in vitro antifungal susceptibility testing for yeasts is not as well established as antibacterial testing, susceptibility from bloodstream or invasive isolates can be helpful in the management of infections, especially if the patient will require transition to longer-term oral therapy. Long-term treatment with newer azoles may be valuable in responding patients. Echinocandins cannot be used as monotherapy to treat *Cryptococcus*, other rare yeast (e.g., *Rhodotorula, Geotrichum, Saccharomyces or Saprochaeta* spp.) or Mucorales. Mucorales species are generally susceptible to amphotericin B and posaconazole and isavuconazole, although there are interspecies variations in susceptibility. At present, the benefits of combination therapy outside of cryptococcal meningitis are inconclusive, but one prospective randomized trial suggested that combination therapy with voriconazole and anidulafungin was associated with reduced aspergillosis-associated mortality in patients diagnosed by serum galactomannan.[42] Clinical experience may support the value of extended combination antifungal therapy, especially when a breakthrough invasive mold disease with a spectrum of possible pathogens is wider and the potential for antifungal resistance increased. Molds that often are resistant to amphotericin B but may be susceptible to voriconazole or posaconazole include *Fusarium, Scedosporium* or *Pseudallescheria*, and *Trichosporon*.

Malignancy-Associated Fever and Drug Fever

Although fever usually indicates the presence of infection, relapsing malignancy, autoimmune-granulomatous, or collagen vascular diseases, immunologic drug reactions can also be sources of fever in the immunocompromised host.[43] Malignancy or drug-associated fevers are the most common causes of persistent noninfectious fevers in cancer patients, but these are "diagnoses of exclusion" that require extensive clinical, radiographic, and microbiologic workup for occult infection until a noninfectious cause is considered most likely. All too often, patients receive escalating empiric broad-spectrum antibiotic therapy during this workup, which should be discouraged in clinically stable patients. Several clinical clues may favor a diagnosis of malignancy-associated fever, including (1) a prior history of fever at the time of initial malignancy diagnosis, (2) clinical stability despite prolonged fever, (3) response of the fever to a trial of naproxen.[2] Patients with drug-associated fever often appear clinically well with relative bradycardia during periods of fever. Drug-induced fevers typically develop 1 to 3 weeks after the start of a drug (β-lactams, sulfas, vancomycin, and phenytoin are among the most common inciting agents) and resolve, on average, within 48 hours of drug discontinuation unless the patient also has an accompanying rash. Drug-associated fever with rash and liver function tests or complete blood count abnormalities (e.g., thrombocytopenia and eosinophilia) are often indicative of more severe reactions that should prompt immediate discontinuation or substitution of the likely offending medications.

Cutaneous eruptions, particularly maculopapular exanthema, may be caused by a number of conditions during the treatment of hematological malignancies (e.g., Sweet syndrome, leukemia cutis, engraftment syndrome, viral infection, skin graft versus host disease) that may be erroneously documented as a beta-lactam or sulfonamide drug allergy. More than one-third of immunocompromised patients admitted to US hospitals from 2010 to 2015 had an antibiotic-associated allergy label (AAL) that was be associated with higher readmission rates, increased utilization of restricted antibiotics and longer antibiotic course duration.[42] In similar Australian studies, skin-testing performed in immunocompromised patients allowed for “de-labeled” of the allergy designation in 84% of patients resulting in a 12-fold improvement in appropriate antibiotic prescriptions.[44] Although immunosuppression has the theoretical potential to cause a “false-negative” skin prick or intradermal test primarily in delayed testing, recent clinical experience has not supported this concern and the vast majority of patients will test negative prior to the onset of immunosuppressive therapy.[45] Therefore, beta-lactam and sulfonamide allergy testing, ideally before the start of chemotherapy, could improve the care of the immunocompromised host.

INFECTION MANAGEMENT IN THE HEMATOPOIETIC STEM CELL TRANSPLANT RECIPIENT: A MODEL OF SEVERE IMMUNE DEFICIENCY

HSCT patients are susceptible to a wide range of infections, but the risk for a particular infection depends on a multitude of factors, including the type of transplantation, the length of time since transplantation, and the development of GVHD. A summary of common infections occurring in HSCT recipients is shown in Fig. 94.6.

Pretransplantation Prophylactic Techniques in Hematopoietic Stem Cell Transplant Recipients

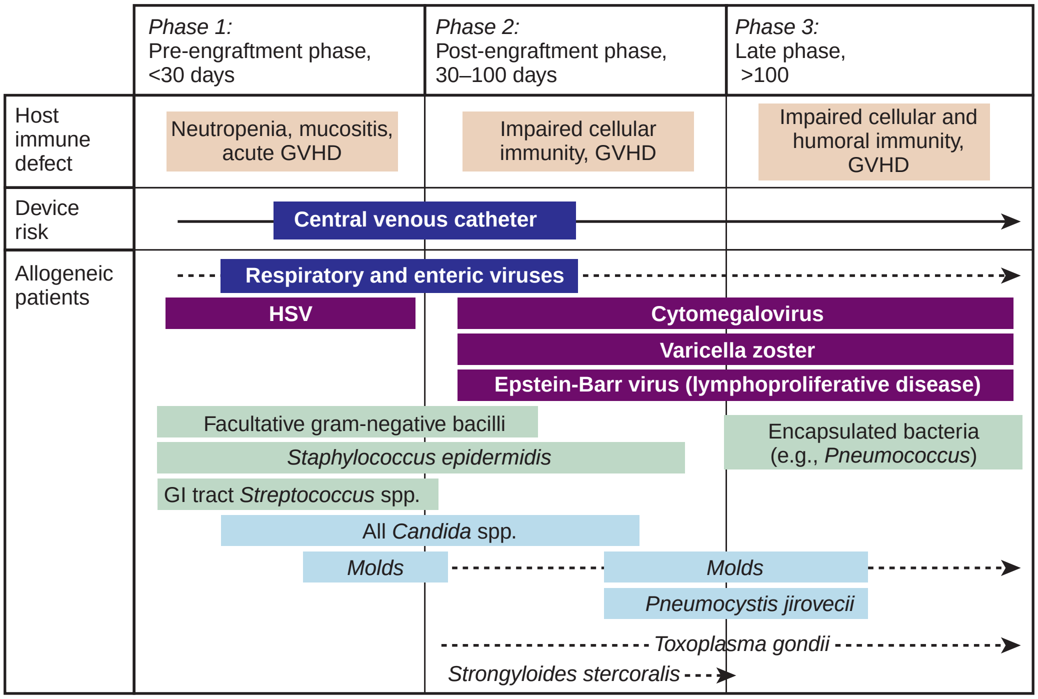
Over the four decades during which HSCT has evolved, antimicrobial prophylaxis regimens have advanced to prevent common or high-risk infections.[3] This is balanced by problems associated with the preventive regimen, including toxicity, overgrowth of resistant organisms, and sometimes high cost. Algorithms for these preventive regimens evolve with changes in epidemiology, diagnostic methods, and new treatment agents for infections. Despite an overall preventive approach, infections still occur when a severe immune defect persists, when the infecting inoculum of organisms is large, when diagnostic methods are not sensitive enough for early detection, or when infecting agents overcome the effect of the antimicrobial agents. Measures taken to prevent infection in the pre-engraftment HSCT patient include pretransplantation serostatus blood workup, environmental measures to prevent infection (including frequent handwashing), and common sense.

Assessment of Pretransplantation Serostatus

Current pretransplant serologic testing of donor and recipient includes assaying for latent viruses (herpesvirus antibodies, hepatitis panels, and human T-cell lymphotropic virus antibodies [human T-lymphotropic virus I/II and HIV 1/2]) and syphilis. Antibody tests that are checked variably among individual transplantation centers include VZV, EBV, and *Toxoplasma*.

Herpes Simplex Virus

Most centers routinely administer prophylactic medication (e.g., acyclovir or oral valacyclovir), which targets HSV for the neutropenic phase of transplantation. HSV lesions can appear as black scabs on the outside of the lips, white- to yellow-based ulcers when found on



Phase 1:
Pre-engraftment phase,
<30 days
Phase 2:
Post-engraftment phase,
30–100 days
Phase 3:
Late phase,
>100
Host immune defect
Neutropenia, mucositis, acute GVHD
Impaired cellular immunity, GVHD
Impaired cellular and humoral immunity, GVHD
Device risk
Central venous catheter
Allogeneic patients
Respiratory and enteric viruses
HSV
Cytomegalovirus
Varicella zoster
Epstein-Barr virus (lymphoproliferative disease)
Facultative gram-negative bacilli
Staphylococcus epidermidis
Encapsulated bacteria (e.g., Pneumococcus)
GI tract Streptococcus spp.
All Candida spp.
Molds
Molds
Pneumocystis jirovecii
Toxoplasma gondii
Strongyloides stercoralis

Figure 94.6 TIMING OF INFECTIONS FOLLOWING HEMATOPOIETIC STEM CELL TRANSPLANT. *GI*, Gastrointestinal; *GVHD*, graft-versus-host disease; *HSV*, herpes simplex virus.

oral mucosa, or as an unusually severe exacerbation of mucositis or esophagitis. HSV prophylaxis administered until recovery from neutropenia may be helpful even in patients receiving nontransplantation chemotherapy such as acute leukemia induction therapy.

Cytomegalovirus

If the transplant recipient is CMV-seropositive before transplantation, they will have a 60% to 70% probability of CMV reactivation and should be followed with periodic (usually weekly) diagnostic PCR monitoring tests for 10 to 20 weeks. If the patient is CMV-seronegative before transplantation but the donor is seropositive, the risk of primary CMV ranges from 20% to 30% and the same monitoring algorithm used for the CMV-seropositive patient is needed.

If the donor and recipient are CMV-seronegative before transplantation, infection through blood products is possible; therefore, exclusive use of CMV-seronegative blood products or other means of preventing CMV seroconversion, such as leukocyte depletion by filtration, are recommended. CMV monitoring should be followed weekly, but the duration of this testing can be shortened by 50%, or by 6 to 10 weeks, because late infection in seronegative recipients is uncommon.

Anti-CMV prophylaxis is often used in high-risk patients. Differences in the mechanism of action of the antiviral drugs should be considered in the interpretation of CMV PCR results. Ganciclovir and valganciclovir, and foscarnet inhibit replication of CMV DNA by interfering with the function of CMV DNA polymerase. Letermovir inhibits terminase complex subunit pUL56 at a stage of maturation and packaging of viral particles distal to viral DNA synthesis. Consequently, free CMV DNA fragments may remain detectable in the blood, and breakthrough CMV DNAemia may not necessarily represent breakthrough infection. However, preemptive therapy with ganciclovir or valganciclovir should be considered for patients on letermovir prophylaxis if CMV DNAeamia continues to arise or is above 150 IU/mL, especially in higher-risk transplants.[46]

Varicella, Human Herpes Virus Type 6, and Epstein-Barr Virus

A history of chickenpox is an adequate surrogate for performing the VZV antibody test. As an alternative to ordering varicella serology on every patient, the test could be ordered in patients with no history of varicella infection or vaccination.

Acyclovir used to prevent reactivation of HSV during neutropenia will also prevent occurrence of clinical VZV infection in most transplantation recipients. Later after transplantation, when acyclovir prophylaxis may have been discontinued, VZV reactivations usually are recognized by their characteristic dermatomal distribution, and treated using acyclovir or valacyclovir.

Serology for HHV-6 is not tested before transplantation because more than 95% of adults are seropositive for the virus. The dose of acyclovir and derivatives used to prevent HSV/VZV is unlikely to have effects of HHV-6 and the clinical significance of detection of HHV-6 in the blood following HSCT is unknown. Meningoencephalitis is the most well-established syndrome caused by HHV-6.

The vast majority of adult patients undergoing transplantation and their donors are EBV seropositive. EBV reactivation leading to post-transplant lymphoproliferative disease is in the differential diagnosis of any new mass, such as enlarged nodes or lung nodules after transplantation (see Chapter 55). Now that sensitive quantitative EBV viral load tests and effective treatments such as rituximab are available, investigators are monitoring high-risk recipients with quantitative viral load studies.[47]

Hepatitis B and C

Hepatitis B (core antibody, surface antibody, and surface antigen) and hepatitis C serologies are tested in donor and recipient before transplantation. Hepatic dysfunction from either hepatitis B or C after HSCT can lead to life-threatening liver complications, including hepatic sinusoidal obstructive syndrome (veno-occlusive disease) and acute hepatic necrosis. Short-term complications are usually due to hepatitis B, whereas the long-term complication of cirrhosis is due to hepatitis C. The risk for hepatitis in the recipient can be reduced by antiviral therapy for recipients and donors who have detectable viral loads, and by transfer of immunity from donor to recipient. A hepatitis-infected individual can be used as a donor if no alternative donor is available or if the intended recipient already is seropositive.

The risk for transmission is small when the hepatitis B–seropositive donor has an undetectable viral load; however, careful follow-up with the recipients is recommended. A surface antigen-positive hepatitis B donor with a high viral load should be treated with lamivudine or another agent to reduce the circulating viral load before transplantation. High-circulating hepatitis C viral load in the seropositive donor for a seronegative recipient is an indication for antiviral therapy of the donor before HSCT.

If the potential recipient has serologic evidence of infection with hepatitis B or C before transplantation, viral load levels should be checked before and monitored after HSCT. High hepatitis B viral load ($>10^5$ copies/mL) is the most important risk factor for reactivation in patients positive for surface antigen undergoing HSCT. High-circulating hepatitis B viral load in the intended recipient is an indication for lamivudine or entecavir. There is no evident correlation between hepatitis C genotype and type or severity of liver disease after transplantation.

Human Immunodeficiency Virus

A positive donor HIV test for a recipient candidate not known to be seropositive is a contraindication for donation. If the screening test for HIV is positive, a Western blot study should be completed to confirm the result because of the potential for false-positive testing.

Syphilis

If the indirect screening test for syphilis returns positive and is confirmed by a direct test, high-dose penicillin treatment should be given for 10 days after transplantation.

Toxoplasma

Historically, 15% of patients who undergo transplantation in the United States are seropositive for *Toxoplasma*, but this percentage may be higher for European centers. The risk for reactivation among seropositive patients is ~2%, for an overall incidence of less than 1% of HSCT recipients. PCR based blood monitoring of seropositive patients prior to starting prophylactic may help with early identification of infection. It is suspected that low-dose sulfa-based regimens, such as those used to prevent *Pneumocystis* pneumonia, may be effective in preventing *Toxoplasma*.

Review of Commonsense Measures to Prevent Infection

Commonsense measures that should be discussed before transplantation or aggressive nontransplantation chemotherapy include attention to diet, travel, crowds, and pets. Additionally, a history of family or social exposure to tuberculosis should be used to guide whether or not an interferon-gamma release assay is applied before therapy.

Diet should be reviewed for herbal supplements or restricted foods. Patients may not recognize that most supplements will have to be discontinued after HSCT. Ground meat products need to be thoroughly cooked so that bacteria, distributed onto meat in the grinding process, are killed. Any fruits or vegetables that cannot be peeled should be washed. Salad bars are associated with occasional transmission of infections. Food products or supplements that inherently contain infectious organisms should be avoided, including undercooked eggs. Blue cheeses have molds spiked into the cheese wheel as they are curing and should be avoided. Soft cheeses carry the potential risk for *Listeria* infection. Yogurt contains *Lactobacillus* that, rather than causing gut problems, has been found to cause infection in other sites, including the lungs after aspiration events.

There are no special travel restrictions, but strategies to minimize transmission of infectious diseases have been summarized. Some social situations, such as sitting in a crowded movie theater or classroom, increase the risk for acquiring a viral illness. Turning away from individuals who are coughing or sneezing may be helpful in preventing the transmission of infections. Patients need instruction to remember to complete the cycle of infection prevention by washing their hands as soon as possible after being close to such an individual. Given outbreaks of noroviruses (Norwalk-like viruses) on cruise ships and other types of outbreaks (e.g., *Staphylococcus*) commonly associated with the close living quarters during this type of travel, cruise ships should be avoided.

Healthy dogs and cats are considered acceptable pets. However, the immunosuppressed patient should not be responsible for scooping cat litter because of potential *Toxoplasma* cyst exposure. Similarly, the patient should not play in sandboxes because these areas are concentrated sites that feral outdoor cats may use as litter boxes. Because reptiles of many sorts have been reported to be infected with *Salmonella*, patients should not touch these animals or the insides or outsides of their cages or tanks. The heated water of tropical fish tanks carry *Mycobacterium marinum*. *Cryptococcus* and *Chlamydophila* (formerly *Chlamydia*) *psittaci* can be transmitted from large pet birds.

Additionally, patients should be counseled about the importance of avoiding activities that may involve exposure to high fungal spore inoculums, such as gardening or composting, vacuuming, smoking tobacco or cannabis, and occupational exposures (farming, demolition/construction, etc.).

Environmental Measures to Prevent Infection

Persons entering the patient's room to perform an examination or touch the patient (including visitors as well as health care workers) should wash their hands outside the room. Ideally, the institution will have handwashing sinks in the hallways outside patient rooms for this purpose. During respiratory virus season, the infection control department often adds extra signs to doorways and other places in the wards to remind visitors of the importance of handwashing. Staff and visitors with symptoms of infection (e.g., cough, fever) should not be permitted to have direct patient contact.

Some infectious situations require special isolation procedures. Contact isolation (gloves and gowns) is used for patients with adenovirus, methicillin-resistant *S. aureus*, or *Clostridium difficile* infection. Droplet precautions are added to contact precautions for respiratory virus or varicella infection. Carriers of vancomycin-resistant *Enterococcus* are placed in contact isolation until they meet defined criteria for discontinuation of isolation.

Laminar airflow is a cumbersome and expensive isolation technique that has been largely outmoded with advances in airflow and isolation technology as well as current antimicrobial therapy. Historically, it has been commonly used for patients with aplastic anemia or those receiving T cell-depleted transplants.

High-efficiency particulate air (HEPA) filtration has replaced laminar airflow as the means for preventing infection through ventilation. With at least 12 air exchanges per hour, HEPA filters can remove particles greater than 0.2 μm in diameter, such as mold spores. Patients often ask whether they should purchase portable HEPA filters for the home or apartment they will occupy after hospitalization. In the broadest sense, this is an extra measure that can be used on an individual basis. If portable HEPA filters are used, they should be placed in each room that the patient will occupy during the day and night, and each unit should be sized for the individual room. A beneficial effect of HEPA filtration in the outpatient setting has not been demonstrated.

Infection in the Hematopoietic Stem Cell Transplant Recipient Preengraftment

The major risk factors for infection in the preengraftment period include drug-induced mucositis, profound neutropenia, and the presence of indwelling catheters. Thus, the major infections observed in this period are due to bacteria that colonize the skin and GI tract (e.g., viridans group streptococci and gram-negative bacilli), *Candida*, and respiratory viruses, especially in the winter months (see Fig. 94.6). Reactivation of latent or partially treated fungal infections can also occur, with *Aspergillus* being well recognized. The propensity of patients to develop such infections has led to widespread use of prophylaxis with an antiviral, antibacterial, and antifungal agent during this time period.

Infection in the Hematopoietic Stem Cell Transplant Recipient After Engraftment

Once engraftment has occurred, the major risk factors for infection include immunosuppression used to treat GVHD and mechanical disruption of mucosal barriers, particularly indwelling venous catheters. Viral infections that reactivate after engraftment often are related to defective T cell-mediated immunity and include CMV, adenovirus, and hepatitis viruses. Outpatient HSCT recipients inhale mold spores and *Pneumocystis* cysts from the environment, so common exogenously acquired infections include aspergillosis, mucormycosis, and *P. jirovecii* (previously *carinii*). Bacterial infections associated with defective cell-mediated immunity such as pneumococcosis, nocardiosis, and atypical mycobacterial disease can also occur in association with significant immunosuppression (see Fig. 94.6).

Cytomegalovirus

CMV causes significant morbidity and mortality in transplant patients both directly and indirectly because of its immunosuppressive effects that predispose patients to concomitant or sequential infection with bacterial and fungal pathogens. Use of prophylactic ganciclovir at engraftment usually is avoided because it leads to myelosuppression and possibly a higher incidence of late CMV disease. Alternatively, letermovir lacks myelotoxic and the effects are shown to reduce CMV-related mortality compared to a placebo.[48] Instead, the patient is treated with ganciclovir when weekly PCR DNAemia monitoring test meets a positive threshold. Initial viral load levels do not predict disease. CMV infections are treated with an induction ganciclovir regimen followed by approximately 6 weeks of a maintenance regimen (half the induction dose). The duration of induction (1 to 3 weeks) varies by institution, but in general 1 week is used for low-grade infection, 2 weeks for high-grade infection, and 3 weeks for end-organ disease. A rising viral load, when checked weekly during the first month of preemptive therapy, signals the need for continued induction dosing or repeat induction dosing.

When the end-organ manifestation of CMV is pneumonitis (recovery of CMV from a deep lung specimen along with an interstitial infiltrate on chest radiograph), IVIg is added on an every-other-day basis for the duration of induction. When CMV manifests in an end organ other than the lungs, use of IVIg is not as clearly useful. Some centers add IVIg when the patient's total IgG level falls below 400 mg/dL. Dosing schedules vary from IVIg given once weekly for 3 weeks to every other day for the duration of induction, similar to therapy for pneumonitis. Ganciclovir resistance is uncommon, but when it occurs, foscarnet or cidofovir may be used.

Varicella-Zoster Virus

VZV reactivations from latency (zoster) usually are recognized by their characteristic dermatomal distribution. No temporal pattern is seen, viremia can occur concurrently, and multiple episodes are possible but uncommon. For patients who have been treated for a zoster episode after HSCT, some centers provide acyclovir prophylaxis until 1 year after HSCT. Less common VZV clinical manifestations that can result in severe infection and may require molecular testing or viral culture for diagnosis include hemorrhagic pneumonia, hepatitis, central nervous system disease, thrombocytopenia, and retinal necrosis.

HSCT recipients with a negative or unknown VZV disease history and a significant exposure to active varicella are susceptible to primary VZV infection. For these patients, varicella-zoster immune globulin, if available, can be provided within 96 hours of exposure. Patients with positive serology can become clinically reinfected after exposure and should be provided with acyclovir prophylaxis; however, such patients do not require varicella-zoster immune globulin. Recombinant VZV vaccination is being increasingly identified as effective in preventing VZV reactivation even in transplant recipients

Epstein-Barr Virus

EBV causes a spectrum of scenarios after stem cell transplantation, ranging from asymptomatic but detectable viremia, hemophagocytic syndrome, or posttransplant lymphoproliferative disorder (see Chapter 55). The incidence of EBV-related complications is higher in mismatched donors, patients with T-cell–depleted transplants, and patients receiving intensive immunosuppression (e.g., antithymocyte globulin). Posttransplant lymphoproliferative disorder after allogeneic stem cell transplantation most often is of donor origin. Quantitative EBV viral load diagnostic testing is not standardized, so the algorithms for monitoring and initiation of the treatment vary. Recognition of greater than 1000 viral copies/mL of blood requires investigation, repeated testing, and possibly treatment, especially in high-risk patients. Direct antiviral agents have limited impact on reducing detectable EBV viral loads. General treatment approaches involve reduction of immunosuppression and rituximab or donor lymphocyte infusion (see Chapter 55).

Invasive Mold Infections

Invasive fungal infections are among the most feared complications of HSCT both because of their high mortality rates and the difficulty in establishing a diagnosis. Among the HSCT recipients that were studied at autopsy, yeast and mold infections were common, seen in more than 25% of deaths. The probability of survival is higher in recent years, likely due to newer and more effective agents, as well as nonmyeloablative conditioning. Posaconazole has been shown to be effective in preventing invasive fungal infections during GVHD.[49] Mold spores may initiate a localized infection in the lungs or sinuses that, after intensive immunosuppression for GVHD, may disseminate to the skin, abdominal organs, or central nervous system. Treatment of mold central nervous system (CNS) infections is problematic due to low CNS penetration of many anti-fungals, with voriconazole achieving the most reliable CNS levels. Infection with Mucorales organisms tends to have later onset than infection with *Aspergillus* (after day 90).

Pneumocystis

The most common presenting symptoms of *Pneumocystis* infection are dyspnea, cough, and fever. Definitive diagnosis requires demonstration of the organism in silver-stained specimens (bronchoalveolar lavage or lung biopsy) although PCR testing of bronchoalveolar lavage fluid is used despite concerns of being overly sensitive for low-positive results. Additionally, serum beta-D-glucan has been reported to have excellent sensitivity and specificity for ruling out *Pneumocystis* infection.[50] However, the interpretation should still require clinical context of the clinical condition of the patient. Most patients present between day 40 and day 80 after HSCT, but cases as early as day 12 and as late as 42 months after HSCT have been reported. Once lymphocyte function is reconstituted, *Pneumocystis* infections are rare. Prophylaxis options include trimethoprim-sulfamethoxazole, aerosol or intravenous pentamidine, dapsone, and atovaquone. Among patients treated with dapsone after transplantation, increased red blood cell and platelet transfusion requirements are noted. Prophylaxis is generally discontinued 1 to 2 years after HSCT, or later if immunosuppression is ongoing.

Parasitic Infections

Similar to the early transplant period, toxoplasmosis remains a concern after engraftment, particularly if there is ongoing immunosuppression.

Infection Issues in the Late Posttransplantation Period

Encapsulated Organism Prophylaxis

Penicillin prophylaxis has decreased the incidences of infection-related morbidity and mortality from polysaccharide-encapsulated bacteria (*S. pneumoniae, H. influenzae* type b, *Neisseria meningitidis*). Penicillin-resistant pneumococcal infection has been reported, prompting consideration of alternate prophylaxis such as a change from penicillins to quinolones. Prophylaxis is generally discontinued 2 years after HSCT, or later if GVHD and immunosuppression are ongoing after the 2-year time-lapse. Once the patient is ready for vaccinations, they are given the conjugate pneumococcal, meningococcal, and *H. influenzae* type b.

Vaccination

Recipients of HSCT frequently lose antibody responses to viral and bacterial pathogens previously targeted by childhood vaccination. Although practice varies among transplantation centers, killed-virus vaccines are often given at 1 year after HSCT and live-virus vaccines approximately 2 years after HSCT for patients without GVHD.[6] For adults, Tdap (formulation of reduced-antigen, combined diphtheria-tetanus-acellular pertussis vaccine) has replaced Td (diphtheria-tetanus booster vaccine) as a means for decreasing the adult reservoir of pertussis. For protection against hepatitis, the combined vaccine providing protection against both hepatitis A and B can be used. The efficacy of vaccination is influenced by the time elapsed since transplantation, the nature of the hematopoietic graft, the presence of GVHD, and the use of serial immunization. Guidelines have been published (see Chapter 110, Table 110.4).

CHAPTER 95

PRINCIPLES OF RADIATION THERAPY FOR HEMATOLOGIC DISEASE

Idalid Franco, Daphne Haas-Kogan, and Andrea K. Ng

The approach and utilization of radiation therapy (RT) for the treatment of hematologic malignancies have seen many changes throughout the years. Advances in imaging and technology have allowed for more precise delineation and targeting of disease. This, along with a reduction in radiation doses and treatment volume, have resulted in increased sparing of normal tissues and dramatically reduced short- and long-term toxicities previously associated with RT. With the majority of hematologic malignancies being highly responsive to radiation, RT plays a critical role in disease management. Use of RT ranges from definitive primary treatment to adjuvant therapy in combination with systemic therapies, as well as salvage or palliative therapy in the relapsed/refractory setting. This chapter will detail the historical changes in the application of RT for hematologic malignancies and focus on the current role of RT based on modern staging, systemic therapies, response assessment, and RT delivery. We will provide current recommendations based on clinical evidence and published guidelines. The goal is to equip the hematologist and oncologist with an evidence-based approach to understanding the overall role and clinical applications, including new concepts in modern RT for a wide variety of hematologic malignancies.

HISTORY AND BACKGROUND

Technological advances that are associated with the diagnosis, treatment response evaluation, and delivery of RT in the last several decades have allowed for more precise and personalized treatment applications for patients. Even within the last 30 years, advances in the components of RT delivery have allowed for higher precision in dose composition. The use of more advanced imaging acquisition for staging and planning has allowed for better patient selection and smaller treatment volumes, resulting in high rates of long-term tumor control with reduced normal tissue exposure and the associated short- and long-term complications. The use of combined systemic treatments with RT, including chemotherapy and more recent targeted and immunotherapy, have resulted in improved locoregional control and overall survival (OS). This chapter aims to provide a framework through which the image of radiation will shift from a one-size-fits-all, to the individualized targeted therapy that is currently used in most radiation oncology practices.

Hodgkin Lymphoma and the Changing Landscape

In 1950, Vera Peters was the first physician to definitively show that RT could be used to cure early-stage Hodgkin lymphoma (HL).[1] Until that time, HL was thought to be incurable. Dr. Peters not only showed that high doses of fractionated RT resulted in a 5- and 10-year survival rate of 88% and 79%, but also proposed the importance of a staging system in prognosis. Historically, RT alone was used to treat early-stage HL, through the use of 2D imaging set up to bony landmarks. Extended-field radiation therapy (EFRT) included total nodal irradiation (TNI), mantle and paraaortic/splenic RT, mantle field RT, and inverted-Y field RT. These large-field treatments were associated with significant long-term toxicities, including risks of second malignancy and cardiac diseases. In the 1990s, in the context of combined modality therapy, EFRT was replaced by involved-field radiation therapy (IFRT), which included only involved nodal regions. However, similar to EFRT, IFRT still relied on 2D planning using bony landmarks to set field borders, with largely anterior-posterior beam arrangements, resulting in unnecessary exposure of a large amount of normal tissue. Involved-site radiation therapy (ISRT), the current standard treatment field, uses 3D-based simulation to incorporate the prechemotherapy volume into the clinical target volume, while excluding uninvolved areas and previously displaced organs based on tumor response. Involved-node radiation therapy (INRT), is a special case of ISRT where staging imaging is acquired with the patient in the RT position, using the same breathing instructions and immobilization devices. This typically results in further reduction in the irradiated volume by allowing more accurate target delineation. Pictorial representations of the changes in HL treatment fields over the years are useful in visualizing the substantial changes that RT has encountered over the years (Fig. 95.1). Detailed guidelines on ISRT/INRT approaches for HL have been published and recently updated by the International Lymphoma Radiation Oncology Group (ILROG), available at https://www.ilrog.org/main-st. A Mini-Atlas of case examples, focusing on the technical aspect of RT, has also recently been published by the group.[2]

MODERN RADIATION PLANNING AND TREATMENT TECHNIQUES

There have been significant technological advances since the days of 2D planning and predominantly anterior-posterior beam arrangements to large treatment fields. With the advent of 3D planning, advanced radiation planning and treatment delivery including intensity-modulated radiation therapy (IMRT), proton beam therapy, image-guided radiation therapy (IGRT), and motion management techniques, highly conformal treatment with significant sparing of normal tissue can be achieved while maintaining disease control. IMRT improves conformality of radiation dose to target structures, while limiting doses to surrounding normal tissues by using multiple beams of varying intensities and shapes that change throughout the treatment to precisely irradiate a target. For mediastinal cases, the use of deep-inspiration breath-hold technique displaces the lungs and heart away from the radiation fields and has been shown to result in significantly reduced lung and heart doses. IGRT via daily cone-beam CT imaging results in further reduced doses to critical structures by allowing a narrower expansion of the clinical target volume to planning target volume. More recently, the use of a Magnetic Resonance Linear Accelerator (MR Linac), with its better image quality, its use of non-ionizing radiation, and its ability to adapt the daily radiation as tumor responds, has the potential to further reduce RT volume and normal tissue exposure. For proton-beam therapy, its dose profile with a sharper fall off can decrease unwanted dose to critical cardiac structures. Guidelines on the use of proton therapy for mediastinal lymphoma have been published by ILROG. Ultimately, it is critical that these various advanced radiation treatment approaches be adapted to provide the greatest benefit by accounting for patient characteristic, needs, and treatment goals.

Numerous dosimetric and modeling studies have estimated and quantified the reduction in doses to normal organs, including heart,

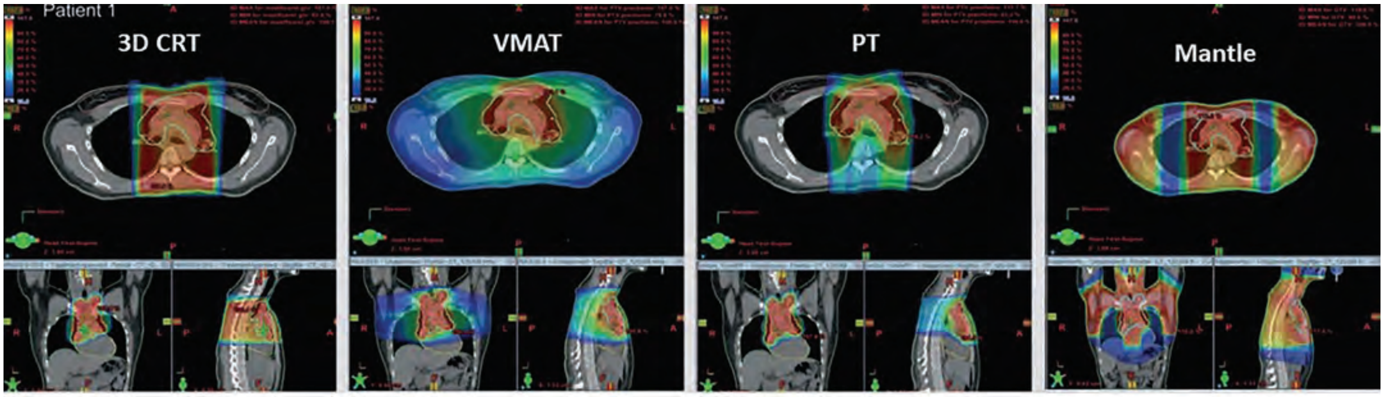
lung, and breasts, using modern fields, doses, and techniques. Fig. 95.2 is an example of a modeling study showing significantly reduced estimated breast cancer, lung cancer, and cardiovascular mortality risks when comparing the historical mantle field with more limited radiation fields and modern radiation technology.[3] There is a growing effort to track volumetric dose estimates to critical normal organs, including cardiac substructures such as left anterior descending artery, heart valves, and cardiac chambers. This will facilitate work on correlating dose-volume exposure of normal organs with late effects, which in turn will guide future treatment and follow-up.

Optimal Use of Imaging

Guidance on optimal use of modern imaging techniques in the staging, planning, treatment delivery, and follow-up of hematologic malignancies was recently published by ILROG. A baseline pre-treatment, [18 F]-fluorodeoxyglucose (FDG) positron emission tomography-computed tomography (PET/CT) is best practice for not only staging but also for RT planning and assessment of response to systemic treatment. Magnetic resonance imaging (MRI) is recommended in tumors of the central nervous system (CNS), head and neck (orbits, paranasal sinuses, and skull base), and skeletal sites to determine and distinguish disease from inflammatory response. Thin CT slices (2 to 3 mm) with IV contrast are also recommended for treatment planning CT to assist in nodal and soft-tissue target delineation. IGRT for verification of accurate delivery of planned dose allows for smaller volume expansion and steeper dose gradients and is recommended for sites where critical organs at risk are in close proximity to the planning target volume, including mediastinum and head and neck regions. Adaptive IGRT with real time shifts are used when there are large changes anticipated in the anatomy or when small changes will result in significant impact on dose distribution.



Risk Estimates	3D-CRT	VMAT	Proton	Mantle

RADIATION THERAPY BY DIAGNOSIS

Hodgkin Lymphoma

HL may present as limited or advanced-stage disease.[4] Limited stage is typically further categorized into favorable and unfavorable prognostic groups. Table 95.1 summarizes the definition of favorable-prognosis disease, according to the German Hodgkin Study Group (GHSG) and European Organization for Research and Treatment of Cancer (EORTC) (see the box with Case 1).

Table 95.2 summarizes the results of the GHSG HD10 and HD11 trials, conducted prior to the incorporation of FDG-PET in guiding treatment decisions.[5] These two trials evaluated treatment de-escalation for early-stage, low-risk, and high-risk patients, respectively. The GHSG HD10 compared 4 versus 2 cycles of adriamycin, bleomycin, vinblastine, and dacarbazine (ABVD), followed by 30 versus 20 Gy IFRT. At a median follow-up of 98 months, no differences occurred in freedom from treatment failure (FFTF) and OS among the four arms, leading to a recommendation of 20 Gy after 2 cycles of ABVD in patients with limited stage, low-risk HL.[6] The GHSG HD11 trial compared 4 cycles of ABVD versus 4 cycles of baseline bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone (baseline BEACOPP), followed by 20 Gy versus 30 Gy of IFRT. At a median follow-up of 106 months, there were no differences in outcome between 20 Gy versus 30 Gy after BEACOPP, but inferiority of 20 Gy after 4 cycles of ABVD could not be excluded. A radiation dose of 30 Gy therefore remains the standard in limited stage, unfavorable HL, after ABVD chemotherapy.[7]

More recent trials have explored using PET-guided response to chemotherapy to further de-escalate or escalate therapy. Table 95.3 summarizes results of these trials, focusing on the elimination of RT, based on PET-guided response or early PET-response to chemotherapy. The RAPID trial compared combined modality therapy with chemotherapy alone in stage I-IIA non-bulky patients with complete PET-response (Deauville 1–2) after 3 cycles of ABVD.[8] At a median follow-up time of 60 months, by intent-to-treat analysis, the 3-year, progression-free survival (PFS) rate was 94.6% in the RT group and 90.8% in the non-RT group ($P = .16$). Although the difference was not statistically significant, the pre-specified, non-inferiority margin of 7% points was not met and hence, non-inferiority of chemotherapy alone could not be concluded. Moreover, by per-protocol analysis, after excluding patients who were randomized to the RT arm but did not receive the treatment, there was a significant difference between the arms in favor of RT (3-year PFS 97.1% vs. 90.8%, $P = .02$). The EORTC/LYSA/FIL H10 trial examined adapting therapy in early-stage patients, according to early PET response to ABVD. For patients with favorable prognosis disease who achieved early complete PET response to ABVD, the 5-year PFS of the combined modality therapy arm was significantly higher than that of the chemotherapy alone arm (99%, vs. 87.1%). For patients with unfavorable prognosis disease, the corresponding 5-year PFS of the two arms were 92.1% and 89.6%, respectively. The difference was not significant but the pre-specified, non-inferiority margin was not met; hence, non-inferiority of chemotherapy alone could not be concluded.[9] For patients with interim PET-positive disease, compared to the standard arm of ABVD followed by INRT, the 5-year PFS of intensifying therapy to dose-escalated BEACOPP or BEACOPP-14 followed by INRT was significantly higher (90.6% vs. 77.8%). However, escalating treatment to BEACOPP was associated with significantly higher rates of grade 3 and 4 hematologic toxicities. The GHSG HD16 trial randomized limited-stage, low-risk HL to 2 cycles of ABVD followed by 20 Gy IFRT, versus the PET-guided treatment arm of 2 cycles of ABVD, with omission of RT if PET negativity was attained after chemotherapy. At a median follow-up time of 45 months, among patients with PET-negative scan at the end of chemotherapy, 5-year PFS was 93.4% for the RT arm and 86.1% for the non-RT arm, leading to the conclusion, similar to the RAPID and EORTC/LYSA/FIL H10 trials, that RT cannot be safely eliminated despite complete PET response to ABVD chemotherapy.[10] The GHSG HD17 trial randomized limited-stage, high-risk HL patients to 2 cycles of escalated BEACOPP and 2 cycles of ABVD, followed by 30 Gy IFRT, versus the PET-guided treatment arm of the same chemotherapy, with omission of RT if PET negative after the chemotherapy and 30 Gy INRT if PET positive. At a median follow-up time of 46 months, the 5-year PFS of the standard arm of combined modality therapy was 97.3% versus 95.1% in the PET-directed therapy arm, demonstrating non-inferiority for the PET-stratified treatment approach. This is the first randomized trial in early-stage HL that showed that RT can be eliminated if complete response to chemotherapy, though the chemotherapy that was used included escalated BEACOPP, which is not a commonly used regimen, especially among early-stage patients in the United States. Of note, the GHSG HD17 is also the first study comparing INRT with IFRT in a prospective randomized fashion.[11]

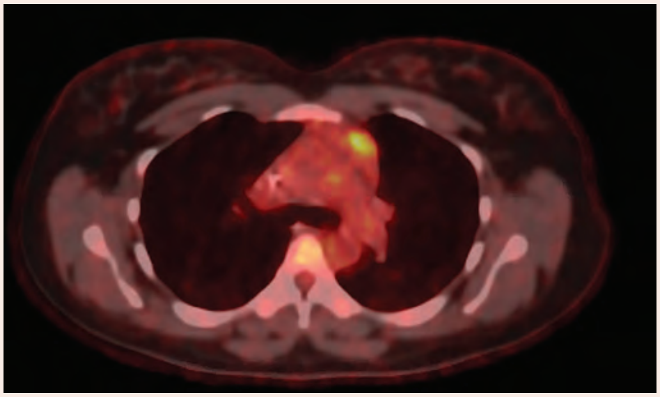
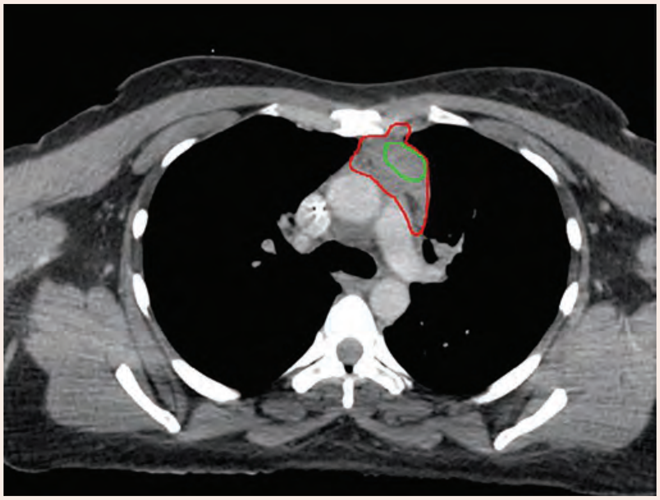
The role of RT for patients with advanced-stage HL is less well defined. The GHSG HD12 trial is a four-arm study for patients with bulky-stage IIB and stages III-IV disease, comparing two different BEACOPP variants with or without RT. Among the patients with initial bulky disease (>5 cm) or residual disease after chemotherapy (>1.5 cm), patients randomized to the non-RT arm had a significantly inferior 10-year PFS in comparison to patients on the RT arm (83.5% vs. 88.6%). In the subgroup of patients with residual disease (>1.5 cm), patients on the non-RT arm had both a significantly inferior PFS (83.4% vs. 89.7%) and OS (88.4% vs. 94.4%). Using PET-guided response to chemotherapy for RT decision in advanced HL was addressed in several trials. In the GHSG HD15 trial, after dose-escalated BEACOPP and its variants, RT was limited to patients with residual disease of 2.5 cm and with residual PET avidity. The 4-year PFS in patients with complete response or those with PET-negative disease/partial response, after chemotherapy and non-RT, were 92.6% and 92.1%, respectively, showing that in patients with complete metabolic response to BEACOPP, excellent results can be achieved without RT. In the GITIL/FIL HD 0607 trial, patients with a negative PET scan after 2 cycles of ABVD continued on to a total of 6 cycles of ABVD; those with a large nodal mass at diagnosis (≥ 5 cm), who continued to be PET-negative, were randomly assigned to RT or no further treatment. At a median follow-up of 3.6 years, there was no difference in 3-year PFS between the two arms (97% vs. 93%; $P = .29$). When the analysis was limited to the subgroup of patients with large nodal mass of greater than 10 cm, the 3-year PFS rates were 94% versus 86% ($P = .34$), although the comparison in this subgroup may be limited by inadequate power. Routine addition of RT, after chemotherapy, in patients with advanced-stage HL is not supported by available data but should be considered in patients who lack complete metabolic response to modern chemotherapy.

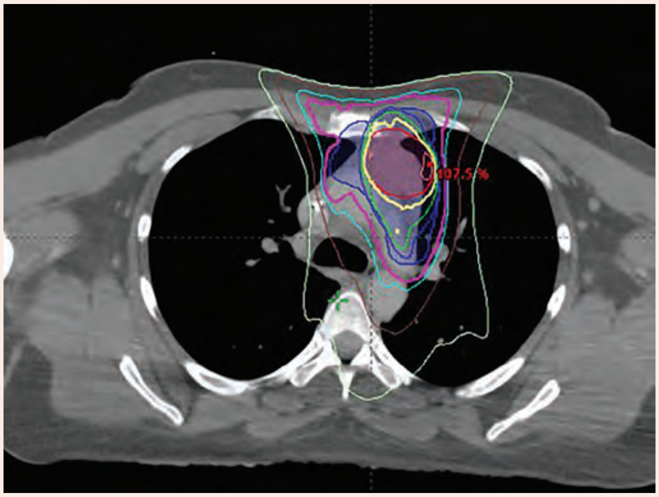
CASE 1

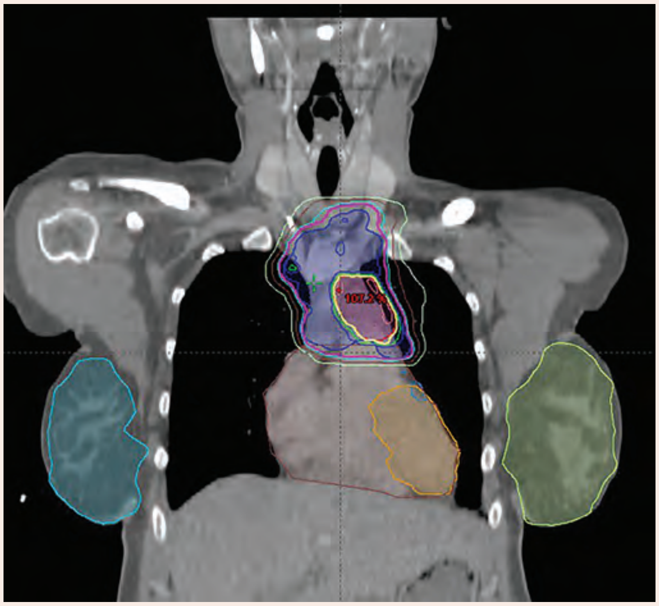
A 28-year-old female with classic Hodgkin lymphoma with Deauville 4 response to chemotherapy:



The patient received involved site radiation therapy (ISRT) to 30 Gy (in 1.5 Gy per fraction, CTV_30 contoured in red) with simultaneous integrated boost to residual fluorodeoxyglucose avid site to 40 Gy (in 2 Gy per fraction, CTV_40 contoured in green). Patient was planned in arms down position on 10-degree incline board to displace breast tissue inferiorly. Intensity modulated radiation therapy (IMRT) with butterfly technique was used (limiting arcs to narrow angles anteriorly and posteriorly to reduce low-dose bath to breasts and lungs):







Continued

Nodular Lymphocyte Predominant Hodgkin Lymphoma

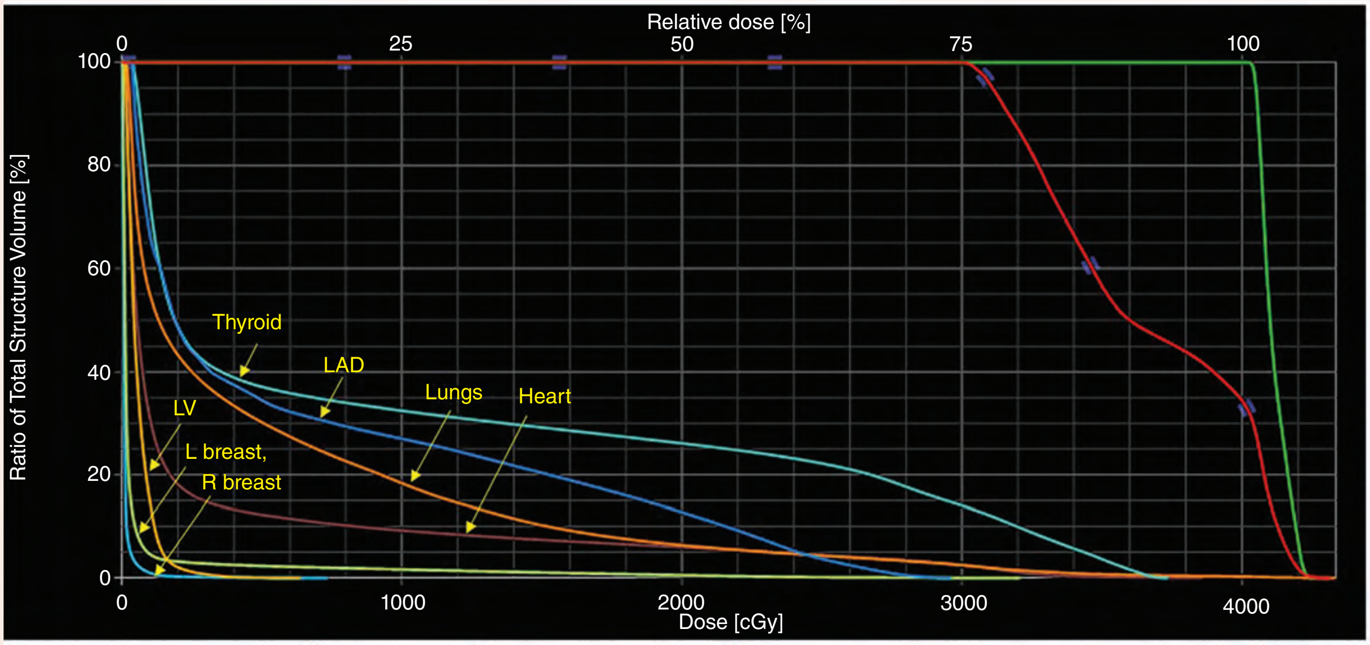
Nodular lymphocyte predominant Hodgkin lymphoma (NLPHL) is rare, accounting for only 5% of all HL cases, half of which present at an early stage. In these early, localized, stage I, or contiguous stage II cases, ISRT may be preferred single-modality treatment. Although the rarity of the disease limits prospective randomized data to guide treatment, large-database studies have shown excellent outcome with the use of RT. A recent large multi-center study, conducted by ILROG, showed a 5-year PFS rate of 91.1% for stage I–II NLPHL treated with RT. Treatment should focus on treating the entirety of the disease, while limiting unnecessary exposure of normal tissues. ILROG guidelines are available and recommend a generous clinical target volume to encompass microscopic subclinical disease and a gross tumor volume (GTV) that is readily visualized. Typical dosing is 30 to 36 Gy in 15 to 18 fractions. Additionally, biopsy confirmation of relapsed disease is strongly advised to rule out transformed lymphoma.

Relapsed/Refractory Hodgkin Lymphoma

ILROG guidelines outlined key indications for incorporating peritransplantation RT, including localized sites of relapsed/refractory disease, bulky disease, incomplete response to salvage therapy, and involvement of sites where local control is critical. Specific emergent situations, secondary to disease progression, include spinal cord compression and superior vena cava syndrome. Depending on the response to salvage therapy, doses of 30 to 40 Gy are recommended. A frequently used strategy is to treat responsive disease sites to 30 Gy and boosting partially responding sites to 36 to 40 Gy. The target volume should be determined on a case-by-case basis, depending on disease location and distribution, but at a minimum should include the site(s) of relapsed/refractory disease, and if feasible, should include adjacent and previously involved sites. Many systemic agents used in HL, either in the upfront or salvage setting, are associated with increased pulmonary toxicity, including bleomycin, carmustine, brentuximab, and immune checkpoint inhibitors. Close attention to

CASE 1—CONT'D

Dose-volume histogram showing doses to organs-at-risk (OAR), and summary table comparing mean doses to OAR with this current ISRT, compared to the typical mean doses to the same OAR in a historical mantle field:



OAR	Mean Dose (Gy)	*Mean Dose with Mantle Field (Gy)*
Lungs	5.1	15–20 Gy
Heart	3.0	20–25 Gy
LAD	6.5	
LV	0.6	
L breast	0.5	15–20 Gy
R breast	0.1	15–20 Gy

lung metrics is especially important in salvage RT for mediastinal HL, and as much as possible, volume of lungs receiving 5 Gy (lung V_5) should be kept below 55%.

Non-Hodgkin Lymphoma

Non-Hodgkin lymphoma is a heterogeneous disease. The two most common histologic subtypes are diffuse, large B-cell lymphoma (DLBCL) and follicular lymphoma (FL). The role of RT in DLBCL is evolving, especially in the era of PET-guided therapy. In FL, RT alone may play a curative role in patients with limited-stage disease. Marginal zone lymphoma or mucosa-associated lymphoid tumor (MALT) is highly responsive to RT; similar to FL, RT alone can be curative in patients with limited-stage disease.

Diffuse Large B Cell Lymphoma

Current standard of care for DLBCL is systemic treatment with rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone (R-CHOP) and has typically consisted of 6 cycles of chemotherapy. However, in patients with limited-stage disease, results of the FLYER trial, randomizing patients aged 18 to 60 years with limited stage, low-risk (normal serum lactate dehydrogenase concentration, ECOG performance status 0 to 1, and without bulky disease [<7.5 cm]) DLBCL to 6 versus 4 cycles of R-CHOP, showed that 4 cycles of chemotherapy plus two doses of rituximab are noninferior to 6 cycles. Indications for adjuvant RT are controversial and have evolved over time. Table 95.4 summarizes studies that explored the role of RT after R-CHOP chemotherapy, prior to the routine use of PET, to assess response to chemotherapy. Findings from these studies suggest a role for adjuvant RT in patients with initial skeletal involvement or bulky disease (≥7.5 cm). However, it is notable that two of the studies were retrospective subgroup analyses of prospective trials and thus prone to selection biases. Importantly, there were no PET assessment at the end of chemotherapy.

More recently, a number of studies have become available, addressing the role of RT in the setting of complete PET response to chemotherapy. The LYSA/GOELAMS 02–03 trial randomized patients with non-bulky (<7 cm), limited-stage DLBCL to 4 to 6 cycles of R-CHOP, delivered once every 2 weeks with or without RT, to a dose of 40 Gy if a complete PET response was achieved after 4 cycles and at the end of chemotherapy. At a median follow-up of 64 months, 5-year EFS (89% vs. 92%) and OS (92% vs. 96%) was not statistically significantly different between the R-CHOP arm versus R-CHOP + RT.[12] S1001, a phase II study of non-bulky (<10 cm), limited-stage DLBCL, treated patients with 3 cycles of R-CHOP, followed by interim PET-CT, with PET-negative patients proceeding with 1 additional cycle of R-CHOP and PET-positive patients receiving IFRT, followed by ibritumomab

tiuxetan radioimmunotherapy. With a median follow-up of 4.5 years, the 5-year PFS was 87% and OS was 89%, with only 11% of patients having a positive PET and requiring RT. The authors concluded that R-CHOP × 4 alone, in patients with complete PET response, should be standard of care for limited-stage, non-bulky DLBCL in the majority of patients.[13] A retrospective series from British Columbia Cancer Agency reported on the outcome PET-guided RT in 723 patients with advanced stage DLBCL, treated with at least 6 cycles of R-CHOP, with observation of those with a negative PET-CT at the end of chemotherapy. In patients with PET positive scans, consolidative RT was offered, when feasible. At a median follow-up of 4.3 years, the 3-year time to progression was 83% among PET-negative patients who were treated with chemotherapy alone. The excellent results suggest that RT may not be needed if a complete metabolic response is achieved. In patients with PET-positive disease at the end of chemotherapy, treated with or without RT, the 3-year time to progression rates were 69% and 33%, respectively, reflecting the important role of RT in those who lack complete metabolic response. Among 285 patients with bulky disease (≥10 cm) and among 142 patients with skeletal involvement, the 3-year time to progression rates were similar to those of non-bulky patients, despite omission of RT. A longer follow-up may be needed to confirm the efficacy of chemotherapy alone in these subgroup of patients who

TABLE 95.4 **Studies in Diffuse Large B-Cell Lymphoma that Explored the Role of Radiation Therapy After R-CHOP (Rituximab, Cyclophosphamide, Doxorubicin, Vincristine and Prednisone) Chemotherapy Prior to the Routine Use of Positron Emission Tomography Imaging to Assess Response to Chemotherapy**

may be at higher risk for local recurrence. Based on these recent results, the role of RT in patients with DLBCL is largely limited to patients who lack complete PET response to R-CHOP or R-CHOP-like chemotherapy, although cases with initial bulky disease or dominant skeletal sites of involvement, as well as receipt of suboptimal chemotherapy due to age, comorbidities, or other circumstances might still necessitate or benefit from RT as part of treatment.

In terms of treatment dose, a trial by Lowry et al. showed that at a median follow-up of 5.6 years, there was no difference in freedom from local progression and OS in patients treated with 30 Gy in 15 fractions, compared to 40 to 45 Gy in 20 to 23 fractions.[14] A phase II trial from Duke, using 20 Gy in patients with complete PET response to chemotherapy, showed that with a median follow-up of 51 months, the 5-year freedom from local recurrence was 98%, and the 5-year PFS and OS were 83% and 90%, respectively.[15] This lower dose is currently being studied in a multi-center phase II trial.

Indolent Lymphoma

For patients with limited stage FL, RT alone has been shown in retrospective studies to result in a 10-year DFS of 40% to 50%. An international multicenter study, conducted by ILROG that included only PET-staged patients, found a 5-year freedom from progression (FFP) of 68.9%. Additionally, among patients with stage I disease, the 5-year FFP was 74.1%, suggesting potentially better results of RT in patients who have been more accurately staged.[16] In terms of optimal dose, the prospective, randomized trial by Lowry et al. found no differences in local progression, PFS, or OS, with 24 Gy in 12 fractions compared to the traditional 40 to 45 Gy in 20 to 30 fractions in patients with indolent lymphoma. This resulted in the adoption of 24 Gy as the standard radiation dose for early-stage, indolent lymphomas. TROG 99.03 compared IFRT alone versus IFRT and cyclophosphamide, vincristine, and prednisone (CVP), with rituximab added later in the trial. The addition of systemic therapy to IFRT showed a PFS benefit but no improvement in OS.[17]

The majority of patients with FL present with advanced-stage disease. In these patients, and in patients with recurrent disease, low-dose RT of 4 Gy in 2 fractions provides effective palliation in those with localized symptomatic sites, is associated with minimal toxicity, and can potentially delay the need to start systemic therapy. Multiple retrospective series demonstrated overall response rates of 80% to 90%. Results from the FoRT trial, comparing 4 Gy in 2 fractions versus the 24 Gy in 12 fractions, showed a statistically significant difference in overall response rate between the lower and higher doses (71.4% vs. 81%; $P = .006$), as well as worse PFS (80.4% vs. 93.7%; $P < .001$), indicating that the low-dose approach is generally not appropriate for patients with limited-stage disease as curative intent (see the box with Case 2).[18]

Marginal zone B-cell lymphoma (MZL or MALT) comprises 10% of NHL. The majority of cases are localized at presentation and tend to remain localized for long periods of time. This subtype of lymphoma is highly responsive to RT. Doses of around 30 Gy to involved nodal regions or extranodal sites will yield a local control rate of close to 100%, with a chance of long-term cure in about three-quarters of the patients. Results from the previously described randomized trial by Lowry et al. in which MALT lymphomas comprise 14% of the cases, suggested that 24 Gy is adequate. Relapses tend to occur at other extranodal sites in which MALT lymphomas tend to present or in a non-irradiated contralateral paired organ. The likelihood of achieving a second remission in patients with limited relapses remains excellent with further local RT.

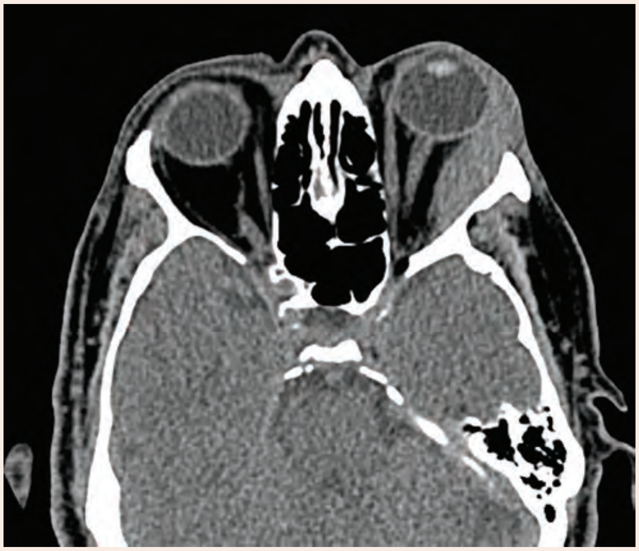
Relapsed/Refractory Diffuse Large B-Cell Lymphoma

In patients with relapsed/refractory DLBCL, results of the landmark PARMA trial, published in 1995, established high-dose therapy and autologous transplantation as the standard for patients with chemotherapy-sensitive disease. The indications of and general approaches to peri-transplant RT are similar to that for relapsed/refractory HL and have been detailed in guidelines put forth by ILROG. One key difference is that for chemotherapy-refractory DLBCL, a higher dose of up to 50 Gy in conventional fractionation, or hyperfractionated approach of 1.3 to 1.5 Gy/fraction twice daily to 35 to 40 Gy, may be needed.

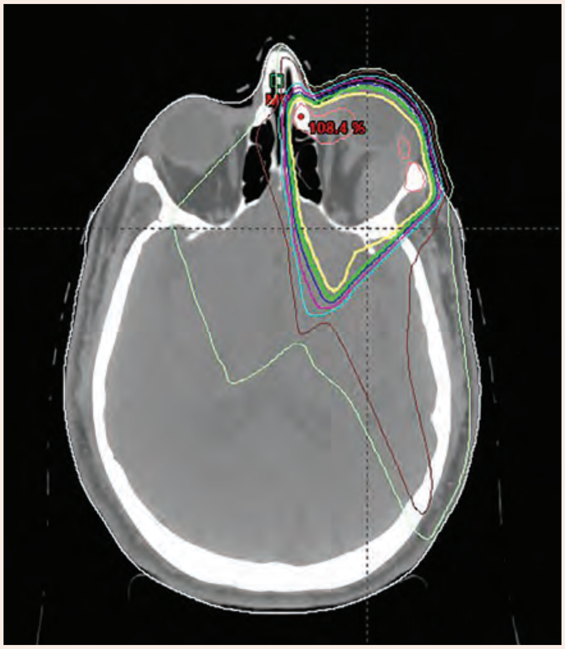
The advent of chimeric antigen receptor T-cell (CAR-T) therapy has changed the landscape in management of relapsed/refractory DLBCL. There is an emerging role for RT as bridging therapy as

CASE 2

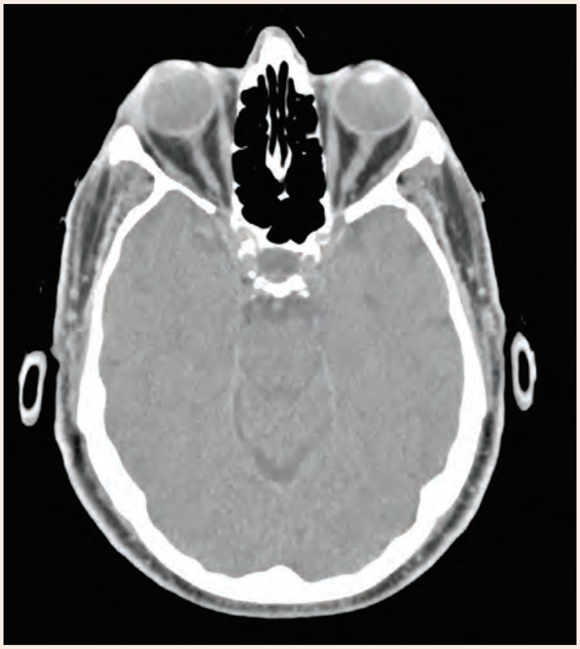
A 70-year-old man with stage IV follicular lymphoma, grade 1 and 2, presented with slowly progressive proptosis and diplopia. Imaging revealed a left lateral rectus mass. Biopsy was consistent with underlying follicular lymphoma:



Low-dose palliative radiation therapy, 4 Gy in 2 fractions was recommended. Aquaplast mask was used for immobilization, and the clinical target volume (CTV) included the entire orbital content. 3D conformal radiation therapy (RT) was used:



The patient noted resolution of proptosis and diplopia approximately 2 weeks after the 2 doses of RT. He did not experience any side effects other than slight fatigue. Follow-up CT scan at 1-year post-treatment showed continued local disease control:



consolidation after CAR-T therapy or as salvage for further relapses after CAR-T therapy. Several small, single institution series, have recently been published, highlighting these approaches. These studies provide early results showing that incorporation of RT to CAR-T therapy is generally safe and provides excellent local response and symptom control, prior to the infusion of CAR-T-cell product. RT may also lead to less severe cytokine release syndrome and neurotoxicity by providing disease debulking. The optimal timing, dose, fractionation schedule, long-term toxicity, and efficacy remain to be determined.

Multiple Myeloma and Plasmacytoma

For patients with multiple myeloma, RT plays an important role in the palliation of painful bone lesions or less commonly soft-tissue disease, lytic lesions at risk for pathologic fractures in weight-bearing regions, and symptoms of cord or nerve root compressions for patients. A dose of 20 Gy in 5 fractions can provide effective palliation, although in cases of cord compression, a higher dose of 30 Gy in 10 fractions may be needed. Solitary plasmacytoma accounts for 5% to 10% of all plasma-cell dyscrasias. For solitary plasmacytoma, RT to doses of 40 to 50 Gy can provide effective local control of over 80%. In cases of solitary plasmacytoma of the bone, about half of the patients will progress to multiple myeloma at 10 years; by 15 years, most will develop multiple myeloma. Extraosseous solitary plasmacytoma is associated with a lower risk of progression to multiple myeloma and has a more favorable disease-free survival. Guidelines from ILROG provide recommendations on optimal RT management in these patients.

Leukemia

Myeloid sarcoma, also known as chloroma, is a rare tumor most commonly seen in the setting of acute lymphoblastic leukemia (ALL) and acute myelogenous leukemia (AML). ILROG guidelines are available on the use of radiation in the setting of CNS relapses, isolated chloroma with inadequate response to chemotherapy, or after hematopoietic stem cell transplant. RT is also used as palliation, including in emergent symptomatic situations, such as cord or nerve root compression. A dose 24 Gy in 2 Gy per fraction can be used in most cases, resulting in excellent and rapid responses, with overall durable control and symptom relief. Doses as low as 6 Gy can provide effective palliation in patients with limited life expectancy.

Total body irradiation (TBI) is used as part of the conditioning regimen for myeloablative or non-myeloablative hematopoietic stem cell transplantation in selected patients with ALL, AML, and other hematopoietic conditions. Technique is variable and based on treatment center. ILROG guidelines list the most common TBI schedules, delivering 12 to 13.5 Gy total over 3 to 4.5 days in 1.2 to 3.0 Gy per fraction. To reduce short- and long-term effects of TBI, interest has been increasing in total marrow and lymphoid irradiation (TMLI), using tomotherapy or volumetric modulated arc therapy (VMAT) techniques to limit target doses to bone marrow, lymphoid tissue, and sanctuary sites.

Skin Lymphoma

Primary cutaneous lymphoma is highly radiation sensitive, with RT playing a major role in its management. The most common type of cutaneous T-cell lymphomas (CTCL) is mycosis fungoides (MF). Total skin electron beam therapy (TSEBT) can provide effective palliation for this disease, and doses of 8 to 36 Gy have been used, with higher doses allowing more durable control. However, a lower TSEBT dose of 10 to 12 Gy is increasingly accepted because of the shorter treatment course, fewer side effects, and opportunity for repeated treatment if needed. The most commonly encountered cutaneous B-cell lymphoma (CBCL), seen in a radiation oncology practice, are primary cutaneous follicle center lymphoma and cutaneous marginal zone lymphoma. In patients with solitary or localized disease, a dose of 24 to 30 Gy can be potentially curative. Otherwise, low doses of 4 Gy in 2 fractions or 8 Gy in 1 to 2 fractions in CBCL and CTCL, respectively, can provide effective local palliation, with complete response rates of 70% to 90%. Details on technique, field, and dose guidelines for the various histologies and clinical scenarios have been published by ILROG.

Rare/Miscellaneous and Special Situations

Primary central nervous system lymphoma (PCNSL) most commonly presents in the brain parenchyma, followed by leptomeninges, spinal cord, and ocular via vitreous and retinal seeding. High-dose methotrexate (HD-MTX)-based induction chemotherapy is considered standard for newly diagnosed PCNSL. The role of RT as part of upfront treatment has been evaluated by several randomized trials. Thiel et al. conducted the first phase III trial, comparing whole brain radiation therapy (WBRT) to a dose of 45 Gy versus non-RT, after HD-MTX-based therapy in PCNSL, showing improved PFS (HR = 0.79, $P = .041$) in the WBRT group but at the expense of higher neurotoxicity; no OS differences occurred between the two arms.[19] More recently, a randomized phase II trial on patients with PCNSL, aged 18 to 60 years, compared WBRT (40 Gy) versus autologous stem-cell transplantation (ASCT) as consolidation treatment after induction chemotherapy. The 2-year PFS rates were 63% and 87% in the WBRT and ASCT arms, respectively, with increased cognitive impairment seen on the WBRT arm.[20] The use of a lower WBRT dose of 23.4 Gy in patients with complete response to HD-MTX was explored in a phase II study from Memorial Sloan Kettering Cancer Center (MSKCC), showing high response rates, long-term disease control, and minimal neurotoxicity. Results of the NRG-RTOG 1114 randomizing patients to low-dose WBRT of 23.4 Gy versus non-RT after chemotherapy were recently presented in abstract form. At a median follow-up of 55 months, the median PFS was 25 months in the chemotherapy alone arm, and it was not reached in the chemotherapy and WBRT arm ($P = .015$). The 2-year PFS were 54% and 78%, respectively. Neurotoxicity rates were not significantly different between the two arms. However, additional neuropsychological testing and neuroimaging analyses are still ongoing to fully characterize cognitive decline associated with the WBRT treatment.[21]

Extranodal natural killer (NK)/T-cell lymphoma, nasal type, is commonly seen in East Asia but rare in North America and Europe. Approximately, 80% of cases involve the nasal cavity and present as erosive and destructive lesions. In patients with localized disease, the treatment approach is non-anthracycline-based chemotherapy regimens, including etoposide and L-asparaginase, in combination with RT. A commonly used regimen in the United States is RT concurrently with 2/3 dexamethasone, etoposide, ifosfamide, and carboplatin (2/3DeVIC). To facilitate radiation target volume delineation, in addition to PET-CT, MRI is important for an accurate determination of soft-tissue disease extent in radiation planning. Radiation dose of 50 to 54 Gy in conventional fractionation is recommended. In the setting of locally-advanced or stage IV disease, the dexamethasone, methotrexate, ifosfamide, L-asparaginase, and etoposide (SMILE) regimen, with sequential RT as indicated, can provide effective disease control.[22]

Primary mediastinal B-cell lymphoma (PMBL) is a distinct clinicopathological entity of lymphoid malignancies, originating from B-cells of the thymus. A phase II trial from the National Cancer Institute found excellent outcome, using 6 cycles of dose-adjusted etoposide, prednisone, vincristine, cyclophosphamide, doxorubicin, and rituximab (EPOCH-R) but without RT. At a 5-year median follow-up, the EFS and OS rates were 93% and 97%, respectively. In a recent abstract reporting on the subgroup of 131 PMBL from the previously described UNFOLDER trial, patients assigned to the RT arm after R-CHOP chemotherapy had a superior 4-year EFS (94% vs. 78%; $P = .007$), mostly due to a higher partial response rate in the non-RT arm, triggering RT but no difference in PFS (95% vs. 90%) or OS (98% vs. 96%).[23] The role of mediastinal RT, after a complete PET response to rituximab-containing chemotherapy regimens in patients with PMBL, is currently being addressed by the International Extranodal Lymphoma Study Group (IELSG) 37 trial.

Primary testicular lymphoma, usually pathologically diagnosed as an extranodal DLBCL of the testis, affects primarily men over the age of 50. There is a high propensity for CNS relapses, and as such CNS prophylaxis with either intrathecal or intravenous methotrexate is included as part of upfront treatment. In addition, there is an increased risk of contralateral testicular relapse, occurring in 15% of patients at 3 years, with an increase to 42% at 15 years. Prophylactic scrotal irradiation of 25 to 30 Gy in 10 to 15 fractions can significantly reduce the risk. A phase II study by the IELSG showed that with the addition of intrathecal methotrexate to R-CHOP chemotherapy and 30 Gy of RT to the contralateral testis the cumulative risk of CNS relapse was reduced to 6%. No contralateral relapse was seen in the 53 treated patients.[24]

DOSE CONSTRAINTS AND TOLERANCES

When considering dose constraints and tolerances in the setting of hematologic malignancies, it is important to keep in mind the young age of a significant proportion of patients, often with highly curable disease and a long-life expectancy. Minimization of doses to surrounding organs-at-risk is therefore especially important, aiming for the lowest possible dose to normal structures, while maintaining adequate target coverage using modern radiation technology. Moreover, because of the modest doses of radiation typically used in the treatment of hematologic malignancies, dose constraints used in solid tumors do not apply to most lymphoma patients. Another important consideration is that many hematologic malignancy patients presenting for RT may have previously been exposed to one or more lines of systemic therapies, with toxicities to specific organs, including heart, lungs, gastrointestinal track, CNS, and bone marrow. Depending on the site of irradiation, special attention to organs that are at risk for overlapping toxicity needs to be made. Table 95.5 summarizes dose constraints recommended by ILROG for mediastinal lymphoma RT.

SUMMARY OF GUIDELINES

Tables 95.6 and 95.7 list the current recommended dose and fractionation for curative and palliative RT, respectively, based on ILROG published guidelines. References to the ILROG published guidelines are listed under suggested readings.

FUTURE DIRECTIONS

As advances in technology continue to improve the prognosis of lymphoma, special attention will be necessary to optimize outcomes, while reducing unnecessary harms. The importance of patient selection and evaluation of individualized de-escalation or intensification approaches based on treatment response, will require a team-based approach. Emphasis on individualized treatment recommendations will continue to require the integration of multidisciplinary teams, with consideration of individual patients' presentation, clinical picture, and goals of care.

TABLE 95.5 Dose Constraints for Organs at Risk Based on Proton Therapy Use in Mediastinal Lymphoma

	Dose Constraint		
Organ	**Ideal**	**Unacceptable**	**Avoid Max Dose To**
Heart: left ventricle, coronary arteries, valves[a]	Mean <5 Gy	Mean >30 Gy	Coronary vessels
Lung[a]	Mean <10 Gy V_5 <55% V_{20} <30%	Mean >13.5 Gy V_5 >60%	—
Breast (age dependent) [a]	Mean <4 Gy	Mean >30 Gy	Glandular tissue
Thyroid[a]	V_{25} <62.5%	—	Whole thyroid

[a] Doses obtained from *Guide to acceptable dose, volume, and field considerations* (Table 2) in Dabaja BS, Hoppe BS, Plastaras JP, et al. Proton therapy for adults with mediastinal lymphomas: the International Lymphoma Radiation Oncology Group guidelines. *Blood*. 2018;132(16):1635–1646.

TABLE 95.6 Summary of the International Lymphoma Radiation Oncology Group Guideline Recommendations for Hematologic Malignancy Cases Treated with Curative Intent

Histology and Stage	Systemic Tx	Total Dose (Gy)	Number of Fractions
Hodgkin Lymphoma—Limited Stage, Favorable	ABVD × 2	20	10
Hodgkin Lymphoma—Limited Stage, Unfavorable	ABVD × 3–4	30	15
Relapsed/Refractory Hodgkin Lymphoma	Salvage chemotherapy, ASCT	Peri-transplant RT: If CR, 30–36 Boost to PR site(s): 36–40	20
Nodular Lymphocyte Predominant Hodgkin Lymphoma—Limited Stage	None	30	15
Diffuse Large B-Cell Lymphoma (DLBCL)	R-CHOP × 3–6	If CR, 30 If PR, boost to 40–45	15 20–25
Indolent Lymphoma—Limited Stage	None	24	12
Natural Killer (NK)/T-cell Lymphoma	Non-anthracycline-based chemotherapy, e.g., DeVIC SMILE	Concurrent or sequential with chemotherapy: 45–54	25–30
Cutaneous Lymphoma, Solitary	None	24–30	12–15
Solitary Plasmacytoma	None	40–50	20–25

ABVD, Adriamycin, bleomycin, vinblastine and dacarbazine; *ASCT*, autologous stem cell transplantation; *DeVIC*, dexamethasone, etoposide, ifosfamide and carboplatin; *RT*, radiation therapy; *SMILE*, dexamethasone, methotrexate, ifosfamide, L-asparaginase and etoposide.

TABLE 95.7 Summary of the International Lymphoma Radiation Oncology Group Guideline Recommendations for Hematologic Malignancy Cases Treated with Palliative Intent Radiation Therapy

Histology	Total Dose (Gy)	Number of Fractions
Aggressive Non-Hodgkin Lymphoma (NHL)	8–30 (depending on performance status, life expectancy, treatment site, prior radiation therapy history)	1–10
Multiple Myeloma	20 30 (if cord compression)	5 10
Follicular Lymphoma, Marginal Zone Lymphoma	4	2
Myeloid Sarcoma/Leukemia	24 Limited life expectancy: 6	12 3

CHAPTER 96

GRADING AND TOXICITY MANAGEMENT AFTER IMMUNE EFFECTOR THERAPY

Emily C. Ayers, Noelle V. Frey, and Daniel W. Lee

The growing use of novel immunotherapies has revolutionized the management of hematologic malignancies over the past several years. While historically cytotoxic chemotherapy has been the standard treatment approach, newer cellular therapies have demonstrated promising activity in patients with relapsed and refractory hematologic malignancies and have significantly improved outcomes in this setting.[1,2] The increased use of these innovative therapies has highlighted a set of unique toxicities which are distinct from previously well-understood side effects associated with standard chemotherapy, monoclonal antibodies, or targeted agents. In order to optimize the use of immune effector therapy, clinicians need to understand how best to manage these newly recognized toxicities.

Immunotherapies and cellular therapies, which harness the host immune system to battle tumor cells, include chimeric antigen receptor (CAR) T-cell therapy, bispecific antibodies and their derivatives, T-cell receptor (TCR) modified gene therapies, and CAR-transduced natural killer (CAR-NK) cell therapy. While many of their toxicities are similar, each of these therapies has a different risk profile. For example, genetically unmanipulated viral-specific T cells are generally much better tolerated than effective CAR-T-cell therapies. Despite these differences, this group of innovative therapies share a toxicity profile which should be graded and managed similarly.

CYTOKINE RELEASE SYNDROME

Cytokine release syndrome (CRS) is the most commonly seen toxicity with immune effector therapies and is a term which describes a pattern of clinical signs and symptoms that develop as a result of robust immune activation resultant from a cell-mediated immune response after therapy. This clinical syndrome was recognized in pediatric acute lymphoblastic leukemia (ALL) patients treated with CD19-targeted CAR-T cells who developed fever, tachycardia, and hypotension consistent with a systemic inflammatory response and was subsequently seen following immune effector cell therapy in the adult population. The pathophysiology of CRS originates from the robust and widespread on-target activation and proliferation of engineered T cells and surrounding bystander inflammatory cells followed by the release of inflammatory cytokines and chemokines including interleukin-6 (IL-6), IL-2, IL-8, IL-10, interferon-γ (IFNγ), monocyte chemoattractant protein-1, and macrophage inflammatory protein-1b among others. Data suggests serum IL-6 is likely derived from macrophages, and peak CAR-T-cell and serum IL-6 levels correlate strongly with severity of CRS in clinical studies. The delayed onset of CRS supports the hypothesis that in the days after cell infusion CAR-T cells proliferate and recruit bystander immune effectors, including macrophages, ultimately resulting in the clinical features of CRS.

CRS of any grade has been reported in 37% to 93% of patients receiving CAR-T cells on clinical trials.[1,2] Clinical manifestations must include fever that can be accompanied by other signs and symptoms ranging from mild flu-like symptoms to a severe inflammatory syndrome with hypotension and a capillary leak syndrome causing pulmonary edema, hypoxemia, and if left unchecked, eventually multisystem organ failure. Time of onset may vary depending on the product used but typically occurs within one week of CAR-T-cell infusion and peaks within 1 to 2 weeks after infusion. Timing of CRS onset and duration after bispecific antibody engager therapies are often much faster with the risk period beginning at the start of the product infusion, while those from TCR, CAR-NK, or other novel engineered cells remain to be determined.

GRADING OF CYTOKINE RELEASE SYNDROME

Prior to the development of the consensus grading established by the American Society for Transplantation and Cellular Therapy (ASTCT) in 2019, the National Cancer Institute Common Terminology Criteria for Adverse Events (CTCAE) versions 3 and 4 were used to grade CRS both on clinical trials and in the standard of care practice setting.[3] However, both CTCAE v3 and v4 demonstrated significant shortcomings with regard to grading CRS resultant from cellular therapies and were perhaps more applicable to toxicities from monoclonal antibody therapies. For example, grading outlined in CTCAE v3 assumes CRS onset within 24 hours of T-cell infusion and fails to account for the delayed onset of symptoms seen in clinical practice. The CTCAE v4 scale is dependent upon infusion interruption, which is not applicable to CAR-T-cell treatments.

In response to inadequate CRS grading by the CTCAE, there were a number of attempts to standardize both the definition and grading of CRS across institutions. Lee et al. developed a structured grading system in which CRS severity was categorized by the degree of hypoxia, hypotension, and/or organ dysfunction and linked to a treatment algorithm.[4] The group at the University of Pennsylvania, likewise, devised a grading system in which CRS severity was scaled according to the degree of hypoxia and/or hypotension and was associated with the intensity of therapy required for treatment of these toxicities.[5] Additional grading systems were developed by Memorial Sloan Kettering Cancer Center as well as a multi-institutional group of investigators who adopted the Lee criteria but developed a unique scale for neurotoxicities called the CAR-T-Cell Therapy–Associated TOXicity (CARTOX) score. These CRS grading scales differed from one another in several ways. For example, the Penn scale categorized patients requiring any intravenous fluids or low-dose vasopressors as well as any supplemental oxygen as grade 3 CRS, while many of these same patients would be classified as grade 2 CRS under the Lee criteria. Due to classification differences such as this, the development of a standardized grading system was paramount to allow for comparison of patients treated across institutions.

Most recently, the ASTCT published international consensus grading guidelines in an effort to standardize the definition and grading scale of CRS (Table 96.1). This group defines CRS as “a supraphysiologic response following any immune therapy that results in the activation or engagement of endogenous or infused T cells and/or other immune effector cells. Symptoms can be progressive, must include fever at onset, and may include hypotension, capillary leak (hypoxia), and end organ dysfunction.” In this simplified consensus grading schema, fever is a prerequisite and CRS grade is determined by the degree of intervention necessary to address hypotension and/or hypoxia in patients. An added feature is that grading can be rapidly assessed by any practitioner at the bedside.

TABLE 96.1 Cytokine Release Syndrome Grading

CRS Parameter	Grade 1	Grade 2	Grade 3	Grade 4
Fever	Temperature ≥38°C	Temperature ≥38°C	Temperature ≥38°C	Temperature ≥38°C
		With		
Hypotension	None	Not requiring vasopressors	Requiring a vasopressor with or without vasopressin	Requiring multiple vasopressors (excluding vasopressin)
		And/Or		
Hypoxia	None	Requiring low-flow nasal cannula or blow-by	Requiring high-flow nasal cannula, facemask, nonrebreather mask, or Venturi mask	Requiring positive pressure (e.g., CPAP, BiPAP, intubation and mechanical ventilation)

BiPAP, Bilevel positive airway pressure; *CPAP*, continuous positive airway pressure.
Adapted from Lee DW, Santomasso BD, Locke FL, et al. ASTCT consensus grading for cytokine release syndrome and neurologic toxicity associated with immune effector cells. *Biol Blood Marrow Transplant.* 2019;25:625–638.

MANAGEMENT OF CYTOKINE RELEASE SYNDROME

Patients with all grades of CRS require close monitoring in an inpatient setting with daily physical exam and laboratory tests including a complete blood count, comprehensive metabolic panel, magnesium, phosphorus, coagulation profile, fibrinogen, C-reactive protein, and ferritin. All patients should receive a thorough infectious workup and strong consideration should be given to administering prophylactic or empiric broad spectrum anti-microbials.

The management of CRS ranges from best supportive care, including antipyretics or intravenous fluids, in mild cases to intervention with anti-cytokine-directed therapy such as the US Food and Drug Administration (FDA) approved anti-IL6-receptor monoclonal antibody tocilizumab[4,6] or corticosteroids. Historically, the first wave of clinical trials with CAR-T cells reserved tocilizumab for more severe stages of CRS due to concern that earlier intervention may negatively impact outcomes. However, there is limited data to inform the optimal timing of intervention for CRS, but earlier intervention strategies are the current norm in the commercial setting with ongoing clinical trials investigating the effect of prophylactic tocilizumab.[7]

The use of tocilizumab varies between treatment centers, the population being treated, and the CAR-T-cell product used. Neelapu et al. suggest the use of tocilizumab for grade 1 CRS in the case of a persistent fever or for grade 2 CRS prior to the use of vasopressors if hypotension is refractory to two fluid boluses.[8] In contrast, Lee et al. advocate the use of tocilizumab in grade 2 CRS for elderly patients or patients with significant medical comorbidities, or for any patient with grade 3 CRS with the express aim to prevent grade 4 toxicity.[4] While there are minor differences between treatment algorithms for earlier grades of CRS published by these different groups, the overall consensus recommends the use of tocilizumab with or without corticosteroids as first-line therapy for grade 3 or grade 4 CRS. While final consensus guidelines are still pending, the National Comprehensive Cancer Network (NCCN) recommends use of anti-IL-6 therapy for prolonged grade 1 CRS (>3 days) in adults with comorbidities or for any adult patient with grade 2 or higher CRS (as per ASTCT criteria). The NCCN recommends corticosteroids for patients with persistent symptoms of grade 2 CRS despite 1 to 2 doses of anti-IL-6 therapy and for any patient with grade 3 or 4 CRS.

Other potential therapeutic interventions include corticosteroids or other cytokine-directed therapies. Initial concerns regarding direct toxicity to T cells associated with corticosteroid use, while not validated in the literature, together with the often-rapid improvement seen with tocilizumab have led experts to disfavor steroids as first-line therapy in treatment of CRS for fear of decreasing the efficacy of the CAR-T cells.[9] Corticosteroids should be added to tocilizumab, however, for refractory or severe CRS. Siltuximab is another monoclonal antibody which binds IL-6 directly and, while it is not FDA approved for this indication, it has been used by some centers to treat CRS refractory to tocilizumab and corticosteroids. Other agents that have been used in the salvage setting include anakinra, dasatinib, and cytotoxic therapy such as cyclophosphamide.

Known risk factors for the development of CRS include tumor burden, higher CAR-T-cell dose, type of CAR-T-cell product, as well has high baseline levels of IL-6.[10,11] In addition, CAR-T-cell products using CD28 costimulatory domains may be associated with increased incidence of CRS compared to products with 4-1BB costimulatory molecules, although conclusive evidence is lacking. Our current ability to predict the risk of CRS accurately, however, is not yet refined, and ongoing research aims to identify predictive biomarkers of severe CRS using cytokine profiles.

IMMUNE EFFECTOR CELL–ASSOCIATED NEUROTOXICITY SYNDROME

The second most commonly observed toxicity from immune effector therapy is immune effector cell–associated neurotoxicity syndrome (ICANS), which is seen in 20% to 60% of people following immune effector therapy. In addition to CRS, the ASTCT also published a consensus definition and grading scale for ICANS (Table 96.2). While some early reports included neurologic events as part of systemic CRS, the current consensus approach advocates for distinct grading and management

The pathophysiology of ICANS is less well understood compared to that of CRS but is still thought to be, at least in part, related to supraphysiologic expression of inflammatory cytokines and chemokines. One potential mechanism involves the expression of IL-1 with subsequent activation of by-standing monocytes, cytokine production and T-cell activation, and endothelial cell activation and disruption of the blood-brain barrier.[12] Known risk factors for severe ICANS include increased tumor burden, higher CAR-T-cell doses, and higher T-cell peak expansion values. Some data suggests increased rates of ICANS with CAR structures containing CD28 costimulatory domains compared to 4-1BB, although there is no conclusive evidence to confirm this association.

The clinical phenotype of ICANS can vary widely (Table 96.3). Early symptoms include encephalopathy, dysgraphia, tremor, and expressive aphasia, which is thought to be most specific for ICANS, but can range in severity to include seizure, akinesis, increased intracranial pressure (ICP), and alterations in consciousness including obtundation and coma.[13] While headaches can be associated with ICANS, this symptom is not sufficient for ICANS as the cause can be multifactorial. The onset of ICANS typically occurs after but sometimes concurrently with CRS and can still occur up to 4 weeks after infusion.

TABLE 96.2 Immune Effector Cell–Associated Neurotoxicity Syndrome Grading

Neurotoxicity Domain	Grade 1	Grade 2	Grade 3	Grade 4
ICE Score	7–9	3–6	0–2	0 (unarousable patient and unable to perform assessment)
Depressed level of consciousness	Awakens spontaneously	Awakens to voice	Awakens only to tactile stimulus	Patient is unarousable or requires vigorous or repetitive tactile stimuli to arouse. Stupor or coma
Seizure	None	None	Any clinical seizure focal or generalized that resolves rapidly or nonconvulsive seizures on EEG that resolve with intervention	Life-threatening prolonged seizure (>5 min); or repetitive clinical or electrical seizures without return to baseline in between
Motor findings	None	None	None	Deep focal motor weakness such as hemiparesis or paraparesis
Elevated ICP/cerebral edema	None	None	Focal/local edema on neuroimaging	Diffuse cerebral edema on neuroimaging; decerebrate or decorticate posturing; or cranial nerve VI palsy; or papilledema; or Cushing triad

EEG, Electroencephalography; *ICE*, immune effector cell–associated encephalopathy; *ICP*, intracranial pressure.

TABLE 96.3 Neurologic and Psychiatric Adverse Reactions Reported With Chimeric Antigen Receptor T-Cell Products

Domain	Clinical Signs/Symptoms
Encephalopathy	Cognitive disorder, confusional state, depressed level of consciousness, disturbance in attention, lethargy, memory impairment, leukoencephalopathy, mental status changes, paranoia, somnolence, and automatism
Delirium	Agitation, hallucination (auditory and visual), disorientation, hyperactivity, restlessness, irritability
Headache	Headache or migraine
Anxiety	
Sleep disorders	Insomnia, nightmares
Motor dysfunction	Muscle spasms, muscular weakness, tremor, myoclonus
Cerebellar dysfunction	Ataxia
Seizure

GRADING OF IMMUNE EFFECTOR CELL–ASSOCIATED NEUROTOXICITY SYNDROME

As with CRS, early clinical trials graded neurotoxicity associated with immune effector therapy using the CTCAE system, which included overlapping terms and was vulnerable to a high degree of subjectivity. Prior to the published consensus grading scale by the ASTCT, the CARTOX criteria were developed by a multi-institutional group of investigators with experience in CAR-T-cell therapy in an attempt to overcome the lack of objectivity in the CTCAE grading system. This group created a CARTOX-10 score to evaluate several neurologic domains associated with neurotoxicity including orientation, naming, writing, and attention, as well as guidelines for grading increased ICP and seizures. One limitation of this grading criteria, however, included the need to measure directly the CSF opening pressure or papilledema in patients, which is difficult to do in a standard-of-care setting.

TABLE 96.4 Immune Effector Cell–Associated Encephalopathy (ICE) Score

Domain	Task	Points
Orientation	Orientation to year, month, city, hospital	4
Naming	Ability to name 3 objects	3
Following commands	Ability to follow simple commands (close your eyes and stick out tongue)	1
Writing	Ability to write a standard sentence	1
Attention	Ability to count backwards from 100 by 10	1

Lee DW, Santomasso BD, Locke FL, et al. ASTCT consensus grading for cytokine release syndrome and neurologic toxicity associated with immune effector cells. *Biol Blood Marrow Transplant*. 2019;25:625–638.

The ASTCT consensus modified the CARTOX scale to develop an easily applicable and comprehensive grading system for ICANS. The group altered the CARTOX-10 score to include a measurement of receptive aphasia and termed this tool the Immune Effector Cell–Associated Encephalopathy (ICE) score which specifically evaluates the level of encephalopathy (Table 96.4). However, full grading of ICANS requires assessment of level of consciousness, seizures, motor findings, and ICP in addition to an evaluation of the patient's level of encephalopathy. Of note, the ASTCT consensus grading includes neuroimaging as a means of evaluating for increased ICP to facilitate grading toxicity.

MANAGEMENT OF IMMUNE EFFECTOR CELL–ASSOCIATED NEUROTOXICITY SYNDROME

Similar to CRS, management of ICANS depends upon the severity of the toxicity and varies across institutions. Patients with any grade ICANS should be monitored in a hospital setting and undergo a comprehensive workup including basic laboratories with a complete blood count, comprehensive metabolic panel, magnesium, phosphorus, prothrombin time (PT) and partial thromboplastin time (PTT), fibrinogen, and infectious workup as indicated, including lumbar puncture when feasible. When possible, patients should also receive radiological imaging with either a CT scan or MRI of the brain to assess for any other causes of neurological symptoms. Electroencephalogram should be performed to rule out electrical or subclinical seizures which may upgrade the severity of ICANS and change management.

If grade 1 ICANS is diagnosed, patients can be managed with supportive measures, close monitoring, and a diagnostic workup as described above. While some centers will start prophylactic anti-epileptics, usually levetiracetam, at the onset of early ICANS, this approach has not yet been standardized. For grade 2 or greater, therapy with corticosteroids is the first-line treatment of choice and is generally agreed to be necessary. Though dosing and choice of steroid is actively being debated still, initial management should likely include 10 mg dexamethasone (or the pediatric equivalent) every 6 to 12 hours, given better CNS penetration compared to other corticosteroids, until resolution of symptoms and can increase to doses of 1000 mg methylprednisolone (or the pediatric equivalent) for grade 4 ICANS. Intermediate grades or refractory symptoms to initial steroid dosing should prompt an escalation of dosing or a change to a different corticosteroid or alternative agent such as anakinra. Once ICANS begins to improve, steroids should be rapidly tapered as tolerated. In general, ICANS is frequently slower to resolve even with treatment compared to CRS. It is not uncommon for ICANS to persist for weeks.

Tocilizumab has not been shown to be effective in the treatment of ICANS, likely because it does not cross the blood-brain barrier. There is also a hypothetical concern for increased risk of severe ICANS due to a transient increase in circulating levels of IL-6 with tocilizumab administration. For this reason, tocilizumab is not recommended for the initial treatment of isolated ICANS in the absence of CRS, though it should be used if the severity of CRS demands it. Other potential interventions for severe ICANS include siltuximab and anakinra, a small molecule IL-1 receptor antagonist, although these have not yet been extensively studied.

NCCN guidelines recommend the use of dexamethasone for adults with grade 2 or higher ICANS along with ICU admission for those patients with grade 3 or 4 ICANS. For patients with concurrent CRS, the NCCN suggests tocilizumab for grade 1 ICANS regardless of duration and corticosteroids as previously described.

OTHER TOXICITIES FROM IMMUNE EFFECTOR THERAPY

Less commonly observed toxicities from immune effector therapies include delayed cytopenias, which can persist for more than 30 days in up to 30% of patients.[2,14,15] The etiology is unclear but is potentially related to ongoing CAR-T-cell activity and subsequent disturbance of normal hematopoiesis. The majority of cytopenias resolve with time and are managed supportively with growth factor support for grade 3 to 4 neutropenia (outside the CRS window) and transfusion support for anemia and/or thrombocytopenia.

Cardiac toxicities observed with CAR-T-cell therapies include sinus tachycardia, other arrhythmias (supraventricular tachycardia, atrial fibrillation, and atrial flutter), left ventricular systolic dysfunction, ST-segment changes, elevated biomarkers (NT-proBNP, troponin, and lactate), and profound hypotension requiring inotropic support. For these reasons, echocardiogram and electrocardiography should be utilized during the risk period.

Other notable laboratory and clinical side effects with these therapies include coagulation abnormalities (elevated D-dimer, PT/PTT and decreased fibrinogen levels) associated with both bleeding and clotting events mainly seen within 2 to 3 weeks of T-cell infusion. Frequent monitoring and aggressive plasma and/or cryoprecipitate supplementation may be required to prevent complications.

Electrolyte abnormalities are also seen in association with and without acute kidney injury and include hypophosphatemia, hypokalemia, and hyponatremia. Hypophosphatemia in particular can be profound and often requires aggressive replacement multiple times a day.

Hemophagocytic lymphohistiocytosis (HLH) or macrophage activation syndrome (MAS) has also been seen with CAR-T-cell therapies although the incidence and pathogenesis of this syndrome is unclear given the overlapping laboratory and clinical findings of both CRS and HLH/MAS. Steroids, and managing severe CRS with tocilizumab, remain the standard of care for CAR-T-cell associated HLH/MAS. Though etoposide is used in other forms of HLH/MAS, there is presently no role for its use here.

Additional, and expected, toxicities of CD19 and CD22-targeted CAR-T-cell therapies are B-cell aplasia and resultant hypogammaglobulinemia, particularly in products which have long in vivo persistence. Patients should have immunoglobulin levels monitored periodically and IVIG replacement therapy should be considered depending on age and institutional practices.

CONCLUSIONS

The CAR-T-cell era has brought a new appreciation for the impressive power of the immune system. Exaggerated and superphysiologic CRS events not previously seen on this scale as well as an entirely new constellation of neurologic toxicities, ICANS, have challenged the successful implementation and availability of widespread CAR-T-cell therapy. Seminal discoveries in the management of CRS with tocilizumab followed by development of a broad consensus (ASTCT) for CRS and ICANS definition and grading were necessary steps to commercialization. There are likely other effective approaches to managing, preventing, or mitigating CRS, ICANS, and the other toxicities discussed, so additional study is needed in these domains.

KEY POINTS

1. American Society for Transplantation and Cellular Therapy (ASTCT) consensus cytokine release syndrome (CRS) and immune effector cell–associated neurotoxicity syndrome (ICANS) definitions and grading criteria should be used for all clinical trial and commercial products that engage T cells moving forward.
2. Tocilizumab +/– steroids should be used as the initial intervention for clinically significant CRS. Early rather than late intervention for CRS is preferred.
3. Steroids should be added if a second dose of tocilizumab is needed. Additional agents (provider's choice) should be utilized if more than 2–3 doses of tocilizumab with steroids are required.
4. Steroids, not tocilizumab, should be used for ICANS. Tocilizumab can be added if significant CRS coexists with ICANS.
5. ICANS may present suddenly and after CRS resolves, so all patients need a caregiver at all times for at least the first four weeks after infusion.

CHAPTER 97

IDENTIFICATION AND MANAGEMENT OF CHECKPOINT INHIBITION TOXICITY

Evgeniya Kharchenko and John W. Sweetenham

Checkpoint inhibitors revolutionized cancer therapy and the field of oncology when the first drug of this class was introduced for melanoma treatment. But their therapeutic benefit comes at a cost of immunotherapy-related adverse events (IrAEs).

Checkpoint inhibitors are immunomodulatory antibodies that are used to activate the immune system to detect and destroy malignant cells. Several immune checkpoint receptors are targeted by different immunotherapy agents, such as cytotoxic T lymphocyte-associated antigen 4 (CTLA-4), programmed cell death protein 1 (PD-1), and programmed cell death protein ligand 1 (PD-L1). Different mechanisms of action explain diverse toxicity profiles: patients who are treated with anti-CTLA-4 therapy generally have more severe IrAEs than PD-1 inhibitors,[1] which inhibit T cells in peripheral tissues at later stages of the immune response. The pathophysiological mechanisms of immunotherapy-related toxicity is still unclear, but translational studies suggest that T cells, antibodies, and cytokine responses may be involved.[2]

Immunotherapy agents are currently widely used in patients with hematologic malignancies. Toxicity profiles for these drugs are generally well studied and include dermatologic, gastrointestinal, hepatic, endocrine, hematologic, and other less common complications (Fig. 97.1).[3] It is important to note that at the moment there are no prospective trials on IrAEs management, and all available data are based on clinical experience and retrospective analysis.

Although rare, severe and sometimes fatal toxicities may occur with checkpoint inhibitors.[4] Therefore, there is a strong need for predictive biomarkers for IrAEs. Such biomarkers can potentially identify the group of patients who will tolerate immunotherapy. Biomarkers that are being studied include serum proteins, factors in the tumor microenvironment, as well as genomic predictors of toxicity.

IMMUNOTHERAPY-RELATED FATIGUE AND SYSTEMIC TOXICITIES

One of the most common IrAEs is fatigue. According to different studies it accounts for 16% to 24% of all IrAEs.[5] In general, fatigue is relatively mild and does not have serious negative impact on daily activity and quality of life. Therefore, for most patients, no specific treatment is needed. Severe fatigue is rare for immunotherapy agents. If it does occur it is rational to exclude other fatigue-related causes like cancer progression or endocrine IrAEs.

Systemic toxicities such as fever and chills can be caused by cytokine release syndrome.[6] Usually it is mild and can be treated by anti-inflammatory agents and acetaminophen. Management of an infusion reaction depends on its grade and requires the use of antihistamines and/or corticosteroids, as well as a dose reduction or infusion discontinuation. Life-threatening consequences of this IrAE occur in less than 2% of patients.

DERMATOLOGIC/MUCOSAL TOXICITY

Rash or pruritus appears in approximately 40% of patients receiving PD-1 inhibitors. Usually it develops early in the course of treatment.[7] Rash can present in various forms such as spongiotic dermatitis-like eczema described as maculopapular, faintly erythematous, and pruritic vitiligo. Less common manifestations include lichenoid, eczematous, follicular, or psoriasiform, dermatitides, and bullous pemphigoid.[8] A clinician must rule out other etiologies like infection, an autoimmune condition, or side effect of a different drug. Diagnostic work-up includes patient history and physical examination, blood cell count, liver and kidney tests. In some situations, skin biopsy should be considered. Management of this IrAE depends on the type, affected body surface area (BSA), signs, response to initial treatment, etc. Diagnostic and treatment approaches are well summarized in the American Society of Clinical Oncology (ASCO) guidelines.[9]

1. Grade 1 implies close weekly monitoring without treatment discontinuation. Topical emollients, oral antihistamines, and/or mild-strength topical corticosteroids can be used.
2. Grade 2 also does not require interruption of immunotherapy, but close monitoring is necessary, and therapy should be stopped if symptoms are not resolving to grade 1. Therapeutic strategies include topical emollients, oral antihistamines, and median-to-high-strength topical steroids.
3. Grade 3 requires immediate pause in immunotherapy until the symptoms resolve to grade 1. Management includes the use of emollients, oral antihistamines, and high-potency topical corticosteroids. Initiating methylprednisolone (or equivalent) 1 to 2 mg/kg should be considered, depending on the severity of the symptoms.
4. Grade 4 demands discontinuation of immune checkpoint inhibitors, immediate hospital admission, and dermatologist consultation (with infectious disease specialist if necessary), as well as intravenous corticosteroids.[9]

Oral mucositis associated with immunotherapy can be a therapeutic dilemma especially in patients who received oral corticosteroids for management of other IrAEs. Oral candidiasis remains an important consideration in the differential diagnosis. In some patients improvement can be achieved with oral corticosteroid rinses and lidocaine.

DIARRHEA/COLITIS

Diarrhea and colitis (symptoms include abdominal pain, fever, nausea, vomiting, bloody stool) or radiographic findings of bowel inflammation are well-documented toxicities of immunotherapy agents. These toxicities are more common and better described for anti-CTLA-4 antibodies than for anti-PD-1 agents. Severe colitis occurs with anti-CTLA-4 drugs in up to 7% of patients compared to 1.8% of those receiving anti-PD-1 therapy.[6] Diagnostic work-up includes testing stool sample for *Clostridium difficile*, Salmonella, and other bacterial enteropathogens. Other causes of colitis may include viral infection like cytomegalovirus.[8] Patients with severe, stable, or progressive course should undergo computed tomography.[10] In case of uncertain diagnosis colonoscopy with biopsy should be considered.[2]

Treatment of immunotherapy-related diarrhea and colitis depends on the grade of toxicity.

1. Grade 1 with mild symptoms that last for less than one week can be managed symptomatically: antidiarrheals, bowel rest, adequate fluid, and electrolyte replacement. Short delay in immune checkpoints inhibitors therapy could be considered in individual cases.

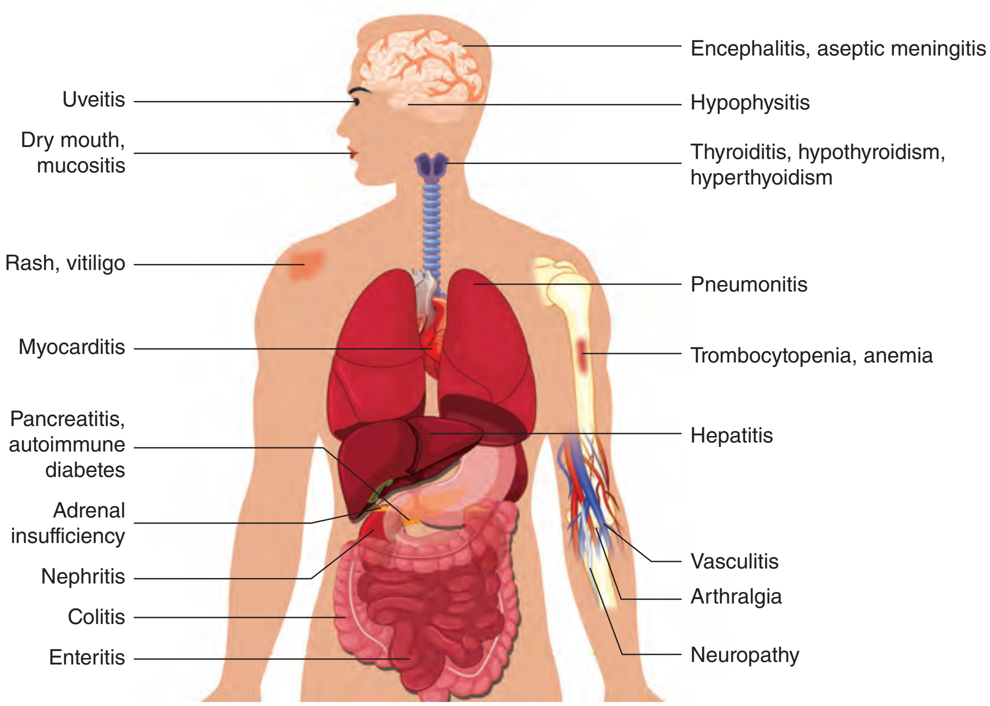

Figure 97.1 Adverse effects of immune checkpoint inhibitors.

2. Grade 2 (4 to 6 liquid stools per day over baseline or abdominal pain, or blood in stool, or nausea, or nocturnal episodes) usually does not require hospital admission, but sometimes is the reason to stop therapy, until the symptoms resolve to grade 1.
3. For severe forms (grade 3 or 4) described as more than 7 liquid stools per day or a life-threatening condition, therapy interruption, hospitalization, gastroenterologist consultation, and corticosteroids 1 to 2 mg/kg are mandatory. The tumor necrosis factor inhibitor infliximab can be used in patients who do not respond to intravenous corticosteroids within 48 to 72 hours.

In a D.H. Johnson et al. analysis, treatment with infliximab was associated with faster symptom resolution compared with corticosteroids alone. In the infliximab group higher-grade colitis were observed (grade 3/4: 86% vs. 34%; $P < .001$), but despite that, median time to diarrhea resolution (3 vs. 9 days; $P < .001$), steroid titration (4 vs. 13 days; $P < .001$), and total steroid duration (median 35 vs. 51 days; $P = .150$) were shorter than in the corticosteroid group (Fig. 97.2).[11]

HEPATITIS

Generally, hepatitis occurs within 8 to 12 weeks after the therapy initiation. According to different reports, immunotherapy-related hepatitis is more common for CTLA-4 than for PD-1 inhibitors (10% vs. 5% respectively).[12] It presents with asymptomatic elevation of aspartate aminotransferase, alanine aminotransferase (AST/ALT). An increase in bilirubin levels and fever are less common.[6,9,13] The grade of toxicity depends on AST/ALT or total bilirubin elevation. Diagnostic work-up includes complete blood count, comprehensive metabolic panel, and stool sampling (culture, *C. difficile* assay, ova and parasite exam). Testing for lactoferrin and calprotectin is optional. The differential diagnosis includes viral hepatitis, alcohol use, medication toxicities, and metastatic liver disease which should be ruled out by appropriate testing which may include[14] computed tomography and liver biopsy. Endoscopic evaluation is highly recommended for Grade 2 cases or higher to stratify patients for early treatment with infliximab based on the endoscopic findings and to determine the safety of resuming anti-PD-1/PD-L1 therapy.

Treatment options for grade 2 hepatotoxicity include withholding immunotherapy until symptoms resolution to grade 1, repeated liver function tests after 1 week, and, if rising, starting prednisone at a dose of 1 mg/kg. In the case of grade 3 toxicity with immune checkpoint inhibitors, therapy should be discontinued, with possible resuming if symptoms resolve to grade 1. If symptoms persist ≥3 to 5 days on oral corticosteroids, consider administering intravenous steroids. Monitoring of AST/ALT and total bilirubin should be done every 48 hours, switching to weekly testing following improvement, until they normalize. Patients refractory to intravenous corticosteroids are rare and they should be treated with mycophenolate mofetil (500 mg every 12 hours). Infliximab should be avoided in patients with elevated AST/ALT since infliximab can worsen hepatotoxicity.[9]

PNEUMONITIS

Pneumonitis is a rare but potentially fatal complication of checkpoint inhibitors. It is usually a therapeutic dilemma, because drug-induced pneumonitis is a diagnosis of exclusion, and other diagnoses, like infection and tumor growth, need to be ruled out.[12,15,16] This IrAE is reported more frequently with anti-PD-1 agents than with anti-CTLA-4 therapy. The median time of symptom manifestation is almost 3 months from initiation of therapy. Clinical presentation is diverse: patients can be asymptomatic or have progressive dyspnea, cough, wheezing, or even be in need of supplemental oxygen.[6] In the diagnostic algorithm, computed tomography is preferred over chest radiography.[12] In moderate and life-threating cases, bronchoscopy should be considered for diagnostic evaluation.

Treatment of immunotherapy-related pneumonitis depends on severity:

1. Mild pneumonitis may only require withholding of immune checkpoint inhibitors and subsequent computed tomography in 2 to 4 weeks.
2. Moderate cases demand immunotherapy interruption and prescription of corticosteroids (0.5 to 1 mg/kg daily).
3. Grade 4 requires complete discontinuation of immunotherapy, intravenous corticosteroids, and possible additional immunosuppression with infliximab, mycophenolate mofetil, intravenous

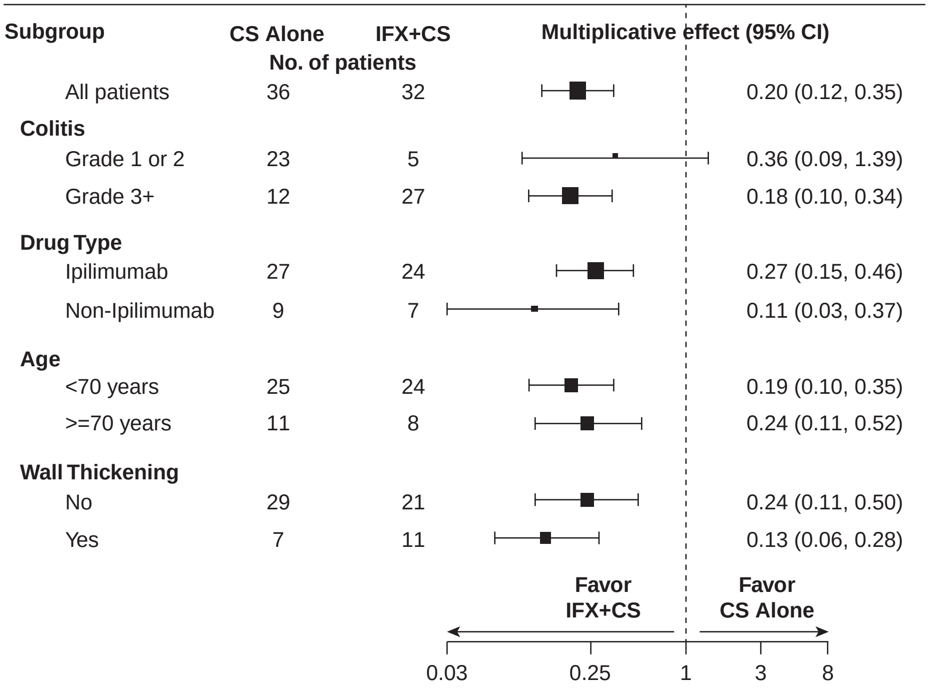

Figure 97.2 Univariate subgroup analysis for the multiplicative effect of irEC treatment (IFX plus CS vs. CS alone) on time to diarrhea resolution. *irEC*, immune-related enterocolitis; *CS*, corticosteroids; *IFX*, infliximab.

immunoglobulin, or cyclophosphamide. Up to 12% of patients with such severe IrAE are resistant to the treatment despite immunosuppression.[12]

ENDOCRINOPATHIES

Several types of endocrinopathies associated with immune checkpoint inhibitors have been reported, such as thyroid dysfunction, hypophysitis, rare primary adrenal insufficiency, and type 1 diabetes mellitus. These conditions could potentially require lifelong hormone replacement, so endocrinologist consultation is essential.[6]

Endocrinopathies manifest as inflammation of pituitary, thyroid, or adrenal glands and result in symptoms like fatigue, nausea, headache, and vision changes. The non-specific course makes these toxicities difficult to diagnose and appropriate treatment can be delayed. Based on available data, endocrinopathies occur in 10% of patients treated with checkpoint inhibitors, with hypothyroidism, hyperthyroidism, and hypophysitis being the most common. Hypophysitis is very rare in patients treated with anti-PD-1 and anti-PD-L1 agents.[17]

Patients who develop hypothyroidism are usually asymptomatic or have mild symptoms like fatigue. Hypothyroidism has an overall incidence of 6.6% and occurs more often with anti-PD-1 than with anti-CTLA-4 drugs.[18] Clinical signs of thyroid dysfunction can be noted with a median of 42 days after therapy initiation.[19] Thyrotropin levels should be monitored, and abnormal numbers are the signs to perform free triiodothyronine and thyroxine testing.[8,20] Management of symptomatic patients with thyrotropin levels greater than 10 mIU/L includes replacement therapy with levothyroxine and endocrinologist consultation. In some cases carbimazole or steroids can be required along with immunotherapy interruption until the symptoms resolve.

Type 1 Diabetes Mellitus

This is a rare complication of immunotherapy which occurs in less than 1% of patients. This IrAE is associated mostly with PD-1 and PDL-1 inhibitors.[21] Blood glucose should be routinely assessed prior to every cycle of therapy. Patients can have different clinical course, ranging from asymptomatic hyperglycemia to diabetic ketoacidosis.[22] Management of immunotherapy-related diabetes includes endocrinologist consultation, lifelong insulin therapy, and temporary withholding of immune checkpoint inhibitors until adequate glucose control is achieved.[9] Benefits of steroids are controversial: they *can* negatively influence diabetes control in these patients.

Rare Immune-Related Toxicities

Some of the IrAEs are extremely rare but worth mentioning due to their potential debilitating effects. These side effects include neurological, cardiac, rheumatological, renal, ocular, and hematological toxicities.

Neurological Adverse Events

Neurological adverse events are reported in 1% of patients receiving immune checkpoint inhibitors and include polyneuropathy, facial nerve palsy, demyelination, transverse myelitis, enteric neuropathy, myasthenia gravis, Guillain-Barré syndrome, and aseptic meningitis. Clinicians should follow general principles for immune-related neurological toxicity: for grade 1 checkpoint inhibitor therapy should be withheld until the nature of the adverse event is defined. For grade 2 to 3 oral corticosteroids should be considered and in case of significant neurological toxicity a switch to intravenous form is required.[23]

Cardiac Toxicity

The incidence of cardiac toxicity is less than 1% and it can present as myocarditis, pericarditis, arrhythmias or cardiomyopathy.[24] It is extremely important to involve a cardiologist into the decision-making process. Early administration of high-dose corticosteroids and immunosuppressive drugs in case of resistance-escalation should be considered.[23]

Rheumatologic Toxicity

Rheumatologic toxicity, which occurs in 2% to 12% of patients, includes myalgias and arthralgias, vasculitis, polymyositis, myositis, and temporal arteritis. Management of grade 1 to 2 (mild or moderate) toxicity is normally limited to paracetamol and/or NSAIDs. Moderate and severe symptoms require prednisolone at a dose of 10 to 20 mg/day or equivalent, and rheumatologist consultation in some clinical cases.[25,26]

Renal Toxicity

Renal dysfunction is rare and occurs in less than 1%. Usually renal toxicity develops 3 to 10 months into therapy.[27] The clinical presentation is not specific and may vary from asymptomatic to oliguria, hematuria, and peripheral edema. Serum sodium, potassium, creatinine, and urea should be measured before every cycle of immunotherapy.[6] Differential diagnosis should rule out contrast nephrotoxicity, volume depletion, or medications. In mild symptoms administration of corticosteroids is usually enough, but in some cases, immunotherapy should be temporarily discontinued. Severe forms of this IrAE require permanent immune checkpoint inhibitor discontinuation and nephrologist consultation.[9]

Hematologic Toxicities

Hematologic toxicity related to immune checkpoint inhibitors includes anemia, neutropenia, thrombocytopenia as well as rare complications like pure red cell aplasia, immune thrombocytopenic purpura, and disseminated intravascular coagulopathy. Cryoglobulinemia and acquired hemophilia A have also been reported.[14] Complete blood cell count should be taken before every treatment cycle. During diagnostics other secondary causes of cytopenias such as bone marrow involvement, hemolysis, medication-induced toxicity, gastrointestinal bleeding, etc., should be ruled out.[28] In case of clinical uncertainty, a bone marrow biopsy should be performed.[6] Common medical approaches used to manage hematologic toxicities are appropriate. This includes initial corticosteroid treatment and use of other immunosuppressive agents in patients refractory to steroids. A detailed algorithm of hematologic toxicities management is well summarized in the ASCO guidelines.[9]

Summary of Toxicity Management

Treatment of the immune-related adverse events is based on the severity of the observed toxicity.

- For grade 1 (mild) toxicity, patients should be carefully monitored during immunotherapy.
- For grade 2 (moderate) toxicity, immunotherapy should be withheld until the symptoms resolve to grade 1 or less. Prednisone 0.5 mg/kg/day or equivalent should be started if a patient is not getting better within a week.
- For grade 3 or 4 (severe or life-threatening) immune-related toxicity, treatment should be permanently discontinued, and patients should be started on high doses of corticosteroids (including intravenous form). In case of resistance to corticosteroid adding immunosuppressive agents is the next step. A proper specialist consultation as well as multidisciplinary evaluation are highly encouraged. Summary of recommendations for immune-related toxicities are well presented in Table 97.1.[23]

Patients-candidates for retreatment after prior immune-related toxicity should be carefully selected. Primarily, the choice should be

TABLE 97.1 Summary of Recommendations for Immune-Related Toxicities

Immune-Related Skin Toxicity

- For grade 1–2 skin AEs, continue (at least 1 week) with ICPis. Start topical emollients, antihistamines in the case of pruritus and/or topical (mild strength) corticosteroid creams. Reinitiate ICPi when grade 1.
- For grade 3 skin AEs, interrupt ICPi and start immediate treatment with topical emollients, antihistamines, and high-strength corticosteroid creams [II, B].
- For grade 4 skin AEs, discontinue ICPi (permanently), consider admitting patient and always consult dermatologist immediately. Start i.v. corticosteroids [1–2 mg/kg (methyl)prednisone] and taper based on response of AE [II, B].

Immune-Related Endocrinopathies

- In symptomatic hyperthyroidism patients, usually grade 1 or 2, interrupt ICPi, start beta-blocker therapy (propranolol or atenolol/metoprolol). Restart ICPi when asymptomatic [IV–V, B].
- In the case of hypothyroidism, rarely > grade 2, start HRT depending on the severity (50–100 lg/day). Increase the dose until TSH is normal. In the case of inflammation of the thyroid gland, start prednisone orally 1 mg/kg. Taper based on recovery of clinical symptoms. Consider interruption of ICPi treatment when symptomatic [IV–V, B].
- In the case of hypophysitis (rarely > grade 2), when headache, diplopia, or other neurological symptoms are present, start (methyl)prednisone 1 mg/kg orally and taper over 2–4 weeks. Start HRT depending on the affected hormonal axis (levothyroxine, hydrocortisol, testosterone) [V, B].
- In patients with type I DM grade 3 to 4 [ketoacidotic (sub)coma], admit to hospital immediately and start treatment of newly onset type I DM [I, A]. Role of corticosteroids in preventing complete loss of insulin producing cells is unknown and not recommended.

Immune-Related Hepatotoxicity

- For grade 2 hepatitis, withhold ICPi and monitor AST/ALT levels closely (1–2 times/week). When no improvement over 1 week, start (methyl)prednisone (0.5–1 mg/kg). Taper over several weeks under close monitoring of AST/ALT and bilirubin [IV–V, B].
- For grade 3 hepatitis, discontinue ICPi and immediately start with (methyl)prednisone 1–2 mg/kg. When no improvement in 2–3 days, add MMF (1000 mg 3_ daily). Taper immunosuppression over 4–6 weeks under close monitoring of AST/ALT and bilirubin [IV–V, B].
- For grade 4 hepatitis, permanently discontinue ICPi, admit patient to the hospital, and initiate (methyl)prednisone 2 mg/kg i.v. Add MMF if no improvement is observed within 2–3 days. Consult hepatologist if no improvement under double immunosuppression. Other immunosuppressive drugs to consider are ATG and tacrolimus. Consult or refer patient to an experienced center. Taper over 6 weeks under close monitoring of liver tests [IV–V, B].

Gastrointestinal Hepatotoxicity

- In patients with non-severe diarrhea (grade 1), ICPi can be continued. Treatment with antidiarrheal medication (e.g., loperamide) should be prescribed [IV–V, B].
- In grade 2 diarrhea, ICPi should be interrupted and the patient should start with corticosteroids depending on the severity and other symptoms (either budesonide or oral corticosteroids 1 mg/kg). In the case of no improvement within 3–5 days, colonoscopy should be carried out and, in the case of colitis, infliximab 5 mg/kg should be administered [IV–V, B].
- In patients with severe diarrhea (grade 3 to 4), permanently discontinue ICPi. Admit patient to the hospital and initiate (methyl)prednisone 2 mg/kg i.v.
- Add MMF if improvement is observed within 2–3 days. Consult a hepatologist if no improvement under double immunosuppression. Other immunosuppressive drugs to consider are ATG and tacrolimus. Consult or refer patient to an experienced center. Taper over 6 weeks under close monitoring of liver tests [IV–V, B].

Immune-Related Pneumonitis

- In grade 1 and 2 pneumonitis, interrupt ICPi therapy, try to rule out infection, and start with prednisone 1–2 mg/kg orally. Taper over 4–6 weeks [IV–V, B].
- In grade 3 and 4 pneumonitis, discontinue ICPi permanently, admit the patient to the hospital, even ICU if necessary, and immediately start high-dose (methyl)prednisone 2–4 mg/kg i.v. Add infliximab, MMF or cyclophosphamide in the case of deterioration under steroids. Taper over a period of 4–6 weeks [IV–V, B].

Continued

TABLE 97.1 Summary of Recommendations for Immune-Related Toxicities–cont'd

Immune-Related Skin Toxicity
Neurological Toxicity
• In the case of mild neurological AEs, withhold ICPi and perform work-up (MRI scan, lumbar puncture) to define nature of neurotoxicity. In the case of deterioration or severe neurological symptoms, admit the patient and start (methyl)prednisone 1–2 mg/kg orally or i.v. In the case of Guillain-Barré or myasthenia-like symptoms, consider adding plasmapheresis or i.v. Ig [V, B].
Cardiac Toxicity
• When a myocarditis is suspected, admit the patient and immediately start high-dose (methyl)prednisone (1–2 mg/kg). In the case of deterioration, consider adding another immunosuppressive drug (MMF or tacrolimus) [V, B].
Rheumatological Toxicity
• For mild arthralgia, start NSAIDs, and in the case of no improvement, consider low-dose steroids (10–20 mg prednisone). In the case of severe polyarthritis, refer patient to or consult a rheumatologist and start prednisone 1 mg/kg. Sometimes infliximab or another anti-TNFa drug is required for improvement of arthritis [V, B].
Renal Toxicity
• In case of nephritis, rule out other causes of renal failure first. Interrupt or permanently discontinue ICPi depending on the severity of the renal insufficiency. • Stop other nephrotoxic drugs. Start (methyl)prednisone 1–2 mg/kg. Consider renal biopsy to confirm diagnosis [V, B].

based on the type and severity of previously developed toxicity as well as on responsiveness to systemic immunosuppression. Careful clinical evaluation is mandatory. In case of anamnesis of life-threatening adverse events (like myocarditis) during immunotherapy, the patient should not be re-offered retreatment. It was reported that retreatment is discouraged in those receiving prednisone 10 mg daily (or equivalent) or higher for treatment of an initial IrAE, because of prednisone association with reduced immunotherapy efficacy.[29] Dose reductions of immunotherapy agents are not recommended for retreatment, as this approach has not been assessed in clinical trials.

Peritransplant Period, Impact on Graft-Versus-Host Disease

Immunotherapy has been used as a bridge for allogeneic hematopoietic stem cell transplantation (allo-HSCT) and in the post-transplant period. Hodgkin lymphoma is the most common indication in patients receiving immune checkpoint inhibitors before and after allo-HSCT. According to available information, administration of immunotherapy in the pre-transplant period is associated with high rates of hyperacute (7%), acute (56%), and chronic (29%) graft-versus-host disease (GVHD). In the post-transplant period immunotherapy shows high efficacy but also increases the risk of GVHD (14%-acute, 9%-chronic).[30]

PATIENTS WITH AUTOIMMUNE DISEASE

In patients with a history of autoimmune disease or a prior reported IrAE, there is a concern of exacerbation of autoimmune disease, return of previously developed IrAEs, or appearance of new side effects. A small number of reports regarding patients with preexisting autoimmune disease are available, because they were excluded from clinical trials. There is an urgent need for prospective clinical trials for this special population. Decision-making should be based on the nature and severity of the autoimmune disease, the organ affected, goals of treatment, therapeutic alternatives, and multidisciplinary team discussion with a proper specialist.[31]

CONCLUSIONS

Immunotherapy has transformed the treatment landscape not only for solid tumors but also for hematologic malignancies. Immune-checkpoint inhibitors provide durable responses and bridge patients to stem cell transplantation. But this group of drugs has its unique toxicity profile which requires special diagnostic and therapeutic considerations. Serious adverse events associated with immunotherapy always need evaluation by the multidisciplinary team and with proper specialists. The following problems remain unsolved: A predictive model for immunotherapy-related toxicity, retreatment after preexisting toxicity, and the effect of immunosuppression on antitumor efficacy. Prospective clinical trials for special groups of patients (such as those with preexisting autoimmune disease) will give us new data and potentially create new therapeutic options for these cancer patients. Ongoing clinical trials expand indications for treatment and future perspectives look promising.

CHAPTER 98

PSYCHOSOCIAL ASPECTS OF HEMATOLOGIC DISORDERS

Hermioni L. Amonoo, Cynthia S. Peng, Rebecca M. Hammond, and Roxanne Sholevar

Major advances in cancer diagnostics and therapeutics have led to increased survival and improved health outcomes for people diagnosed with hematologic malignancies.[1] However, high levels of psychological distress (e.g., depression) and diminished positive psychological well-being factors (e.g., optimism) exist in this population for myriad reasons, including the cancer diagnosis itself, uncertain prognosis, prolonged treatment course that entails numerous hospitalizations with extended periods of isolation, and potential toxicities of treatment.[2] The life-threatening nature of hematologic malignancies also results in existential, social, and economic stressors which can also negatively impact psychological well-being (Fig. 98.1).[3]

Hence, this chapter describes factors that impact psychosocial well-being in patients with hematologic malignancies, the psychologic responses experienced by patients throughout the illness and treatment trajectories, the risk factors for psychological distress, and current evidence for psychosocial interventions that promote psychological well-being.

CLINICAL COURSE OF HEMATOLOGIC MALIGNANCIES

The incidence, course, treatment, and survival for various hematologic malignancies vary widely, yet dramatic improvements in survival rates have been seen almost universally.[1] In contrast to many solid cancers, treatment of hematologic malignancies often involves intense regimens, highly technical therapies, lengthy hospitalizations, high infection risk, periods of unpredictability, and frequent outpatient monitoring of the patient's condition.[2] Robust psychological well-being is essential for each unique aspect of the illness or treatment trajectory.[3,4] Although some patients with hematologic malignancies have the potential for cure via treatments such as hematopoietic stem cell transplantations (HSCTs), others have an initial reduction in tumor burden only to face relapsed disease. Yet, others do not respond to treatment, resulting in a progressive decline despite best efforts with various therapeutic measures. In a minority of patients, the cancer is so advanced at the time of diagnosis that they experience a rapid progression of their disease which results in death.

Time of Diagnosis

Being diagnosed with a hematologic malignancy can be a devastating time of crisis. The time of diagnosis has been described by a cancer survivor as "a lightning bolt through a stop sign" or an existential plight.[5,6] It is a time of intense distress and likened to a personal disaster in the patient's and family's life.[6] Often these patients have experienced vague symptoms such as fatigue for weeks or even months prior to diagnosis with treatment and reassurance for presumed non–life-threatening illnesses. Oftentimes, a large majority of patients may have had their concerns dismissed for many months, and then subsequently the ultimate diagnosis of an unexpected, catastrophic illness can feel even more blindsiding. Moreover, there are multiple personal and cultural factors that may profoundly influence the patient's response to their cancer diagnosis.[7,8] Being aware of the patient's exposure to cancer in the past (e.g., history of loved ones with a cancer diagnosis) and the meaning of their cancer experience may provide insights into their initial response.[8] Despite the inevitable psychosocial challenge of getting diagnosed with a hematological malignancy, it is well documented that many patients ultimately manage effectively with their diagnosis by employing a variety of coping mechanisms and skills.[9]

Although distress at diagnosis can sometimes translate into potential psychiatric diagnoses (e.g., mood disorders), most patients will not develop full-blown psychiatric disorders unless they likely had undiagnosed psychiatric symptoms prior to their cancer diagnosis.[10] Risk factors for a psychiatric disorder at the time of diagnosis include prior psychiatric history, gender, social and psychologic factors, disability, and avoidant coping.[10-14] Careful assessment of the patient's reaction is important, particularly as initial psychological reactions are often predictive of later adaptation and coping in survivorship.[15] Early assessment by clinicians can help to identify patients at risk for adjustment challenges and psychiatric disorders—these patients, in particular, will benefit from early psychological support (Box 98.1).[16–18]

Compared to patients with solid malignancies, patients with hematologic malignancies often need immediate oncologic treatment. The period from the time of diagnosis through the initiation of treatment is characterized by fast-paced medical evaluations and treatment planning—the rushed development of new relationships with unfamiliar medical personnel, and the need to integrate a barrage of information can be at best frightening and confusing.[2] During this time of diagnosis, many providers convey large amounts of information as part of treatment planning. It is not always easy for patients (especially those with limited health literacy) to assimilate the information, prioritize their problem-solving behaviors, and articulate their preferences. Consequently, providers often repeat information at each contact and inquire about the patient's and caregivers' understanding of facts and treatment options. Patients and their caregivers describe a state of numbness during this phase and that information is not thoroughly processed or understood—clinicians must consider this added barrier to communication when counseling patients and their caregivers.[19]

Clinicians have an important role in monitoring and possibly mediating psychosocial adjustment in presenting an initial diagnosis of cancer to patients. If patients have a clear explanation of their condition while encouraged to maintain hope, the initial reaction of shock, fear, and desperation can foster optimism about treatment. Clinician awareness of the unique meaning that patients ascribe to their cancer diagnosis is also vital. Patients who have a pervasive and unyielding negative affect that persists long after the crisis of diagnosis may require ongoing psychosocial monitoring and referral for services and supportive interventions throughout their treatment and disease course.[20]

Caregiver distress assessment during this diagnosis phase is also essential, especially as caregivers are a significant source of social support for patients during treatment and in recovery.[21] Studies have shown that caregivers share similar rates of psychosocial distress.[20,22] Psychological distress is easy to assess in patients and caregivers.[23] Hence, timely evaluation of distress and referral for psychological support during this period is critical to adequate coping throughout the patient's course of illness.

Treatment

Active treatment of cancer usually initiates another acute phase of the cancer experience. Psychosocial factors are critical parameters in

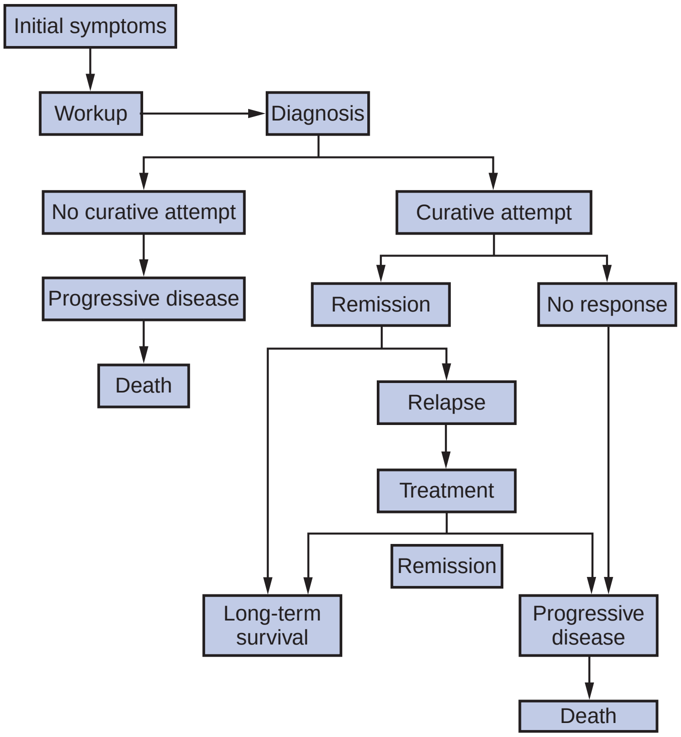

Figure 98.1 CLINICAL COURSE OF A PATIENT WITH A HEMATOLOGIC MALIGNANCY. *(Modified from Lesko LM. Hematopoietic dyscrasias. In: Holland JC, ed. Psychooncology. New York: Oxford University Press; 1998: 408.)*

BOX 98.1 Factors That May Predict Poor Coping in Patients With Cancer (Hematologic Malignancies)

Advanced disease
Higher regimen-related toxicity
Uncontrolled symptoms
Past psychiatric history
Avoidant coping (e.g., escape-avoidance, distancing, and denial)
Substance abuse history
Recent history of smoking
Compliance issues
Demographic factors (e.g., younger age and female sex)
Limited social support or difficult social relationships
Recent losses
Pessimistic outlook on life
Family or interpersonal obligations (e.g., childcare, eldercare)
Lower functional status

deciding which treatment is best for an individual patient and should be considered alongside all aspects of medical/surgical treatments in the development of the treatment plan. Empowering patients in their own treatment by involving them in decision-making can help to mitigate some aspects of the psychosocial distress. Often, patients react to a diagnosis of cancer with feelings of fear and helplessness. In this vulnerable state, patients may believe that complete reliance on the oncologist is necessary. A patient may look to the primary oncologist for a curative treatment that also can preserve their quality of life. Combating feelings of helplessness during this period can help patients alleviate anxiety and possible depression.[12] A member of the clinical team who has established treatment alliance with the patient is best poised to explore distress that could accompany treatment. A concerted effort to partner with patients while balancing patient autonomy during treatment planning can be beneficial. Providing patients and their caregivers with accessible information about their treatment options often alleviates anxiety and uncertainty in empowering them to feel more in control.

It is also important to engage caregivers and families during treatment planning. Caregivers play a crucial role during the treatment phase of cancer care since patients rely on their caregivers to adhere to different aspects of their treatment including follow-up visits, medication management, and maintaining quarantine status.[24] Assessing for economic, social, and relationship stressors among caregivers is also important as these external factors can exacerbate psychological stressors during the treatment phase. Patients and their caregivers should be made aware of the plethora of resources available for support, including patient and caregiver support groups.[25]

HEMATOPOIETIC STEM CELL TRANSPLANTATION

HSCT is a potentially curative treatment for many high-risk hematologic malignancies and nonmalignant diseases either as part of initial treatment or after relapsed disease. HSCT is complex with its own staggering morbidity and mortality, accompanied by significant distress on patients and their caregivers. The transplantation itself is followed by a variably extended recovery period which includes a prolonged 3- to 4-week hospitalization, periods of isolation, significant lifestyle changes, permanent loss of function in some cases, and changes in physical appearance. Psychological distress in HSCT patients is associated with worse health outcomes (e.g., increased mortality and higher risk of graft versus host disease [GVHD]) and psychological stress-related factors are thought to modulate cell engraftment and recovery following transplantation via the hypothalamic-pituitary axis and sympathetic nervous system.[26]

Because HSCT is an intense and distinctive experience for patients and caregivers, it has the potential to cause short- and long-term psychological distress. In recovery, patients face unique medical challenges, including recurrent infections and repeated hospitalizations for weeks to months during their initial recovery.[18] Consequently, a thorough pretransplant psychosocial evaluation is recommended to establish a psychiatric baseline, identify those patients at risk for development of psychological morbidity, and initiate timely psychological support and interventions during the immediate and long-term recovery following HSCT.

Identified risk factors for psychosocial morbidity associated with HSCT include psychiatric history, pretransplant non-adherence to medical treatment, non–transplant-related medical comorbidities, younger age, female sex, recent smoking cessation, lower functioning status on admission, quality of life deficits, perception of limited social support, and the presence of difficult relationships.[16,18] In particular, assessment of substance use and prior adherence with medical care are important in predicting patients' ability to consistently and reliably adhere to the demands and requirements of aftercare during HSCT recovery.

The decision to undergo HSCT can be its own source of psychological distress to patients due to the complexity and demands of the recovery. The existential issues of the anticipated loss of freedom and choice become immediately prominent when patients are presented with the option of HSCT. Despite best efforts by HSCT clinicians to explain probabilities of outcomes, patients often feel overwhelmed with the decision that is ultimately theirs alone. The patient's support network, not limited to family and/or friends may contribute to the burden of this decision-making anxiety, unknowingly or not, through expressing their opinions. Patients may also use their caregivers as objects on which to project their own anxieties and grief. An increased awareness of these factors by HSCT clinicians provides the patient a comfortable and safe space to process these anxieties.

Psychological Considerations in Hematopoietic Stem Cell Transplantation

Anxiety is usually heightened during the conditioning phase (or minus days) of HSCT due to anticipation of how the transplant would be tolerated.[10] The infusion of stem cells can be a special moment for patients, some of whom refer to the date of transplant as a "birthday" or special anniversary date. Some institutions offer a "blessing" of the stem cells by a member of the spiritual care team prior to the transfusion. Patients are sometimes surrounded by family, friends, and caregivers for the transplant. Attention should be paid to any special relationship between the patient and the marrow donor (i.e., related donors in allogeneic transplantations) as that can impact distress levels going into the transplant.

Patients are particularly vulnerable to psychological distress during the engraftment phase due to several factors. First, patients experience a high physical symptom burden including fatigue, nausea, anorexia, pain, diarrhea, and fevers, most of which are side effects from the conditioning regimen. Although some patients attribute these physical symptoms to "healthy" bone marrow, these physical symptoms heighten distress during the transplant hospitalization. Patients are most vulnerable to infection while awaiting engraftment, requiring strict isolation, limiting interactions with friends and family, all of which undoubtedly contribute to distress. Body image (e.g., hair loss, cachexia, steroid-related changes) and functional changes (e.g., severe fatigue, bedridden status, cognitive impairment in setting of delirium) are also sources of significant psychological distress; though these changes (at least in their present severity) are temporary, patients may experience them as a herald of permanent change. Hence, gentle reminders of the typical physical symptom burden associated with the transplant, especially those symptoms that are usually temporary, could reduce patient distress during the engraftment phase.

Khan and colleagues identified the following common psychiatric diagnoses among patients hospitalized for HSCT: adjustment disorder (40%), depression (23%), generalized anxiety disorder (10%), acute psychotic disorder (10%), delirium (10%), and depressive psychosis (7%).[27] Notably, undiagnosed and untreated pre-transplant psychiatric disorders constitute a significant proportion of psychiatric diagnoses identified during the transplantation process.[10] The prevalence of psychological distress that does not meet diagnostic criteria has been identified as even higher: depressive symptoms in 35%, delirium in 35%, and posttraumatic stress disorder (PTSD) in 20%.[10] Kishi and colleagues compared inpatient psychiatric consultations among transplant and nontransplant patients.[28] Transplant patients differed on several characteristics: more frequently White, less likely to have a previous psychiatric history, longer period between admission to consult, more delirium, and more socioeconomic and health-related distress.

Typically, patients perceive their quality of life to be worse during the first year post-transplant compared to their quality of life pre-transplant.[29] The psychological distress patients experience in the acute and chronic post-transplant phases may differ. The first 100 days after transplantation are demanding, with at least twice weekly outpatient visits, and isolation requirements (e.g., restriction from contact with large numbers of people or areas with crowds, including restaurants). Factors associated with distress in the acute post-transplant phase include persistent physical symptoms, slow physical recovery, increased treatment-related toxicity, body image disturbance, and lower performance status.[10,30] In addition, patients often grapple with the fear of relapse and/or secondary malignancies. The post-transplant period could also entail complex medication regimens (e.g., steroids, tacrolimus) that have neuropsychiatric sequelae including but not limited to mood disturbance, anxiety, psychosis, neurocognitive dysfunction, and posterior reversible leukoencephalopathy syndrome. A comprehensive discussion of the neuropsychiatric complications of HSCT is beyond the scope of this chapter.[31]

The chronic post-transplant phase comes with its own set of complications. Although most patients gradually improve their performance status, there is often discordance between the patients' pre-HSCT expectations and the everyday symptoms that limit their physical abilities. Distress associated with cognitive dysfunction is also repeatedly reported by patients as they return to the workplace or reenter school.[25] Educating patients about common short-term neurocognitive side effects can reduce anxiety. Further, neurocognitive side effects of treatment (e.g., diminished concentration, short-term memory loss, decreased speed of information processing, and loss of effective problem-solving abilities) can be long term in high-risk patients but are mostly temporary. Ongoing physical and cognitive impairment often impact longstanding roles in relationships and vocations that can unleash existential anxieties related to isolation and meaning.

Sexual dysfunction is a common long-term side effect of HSCT in the setting of high-dose cytotoxic chemotherapy and total-body irradiation.[32,33] Commonly reported sexual symptoms among HSCT patients include decreased libido, vaginal alterations, erectile and ejaculatory dysfunction, premature menopause, dysregulation of sexual hormones, dyspareunia, and infertility.[34,35] Despite these known symptoms, sexual side-effects are inadequately assessed and managed in patients undergoing HSCT. Clinicians' proactive approach to exploring these problems will help reduce patients' embarrassment about discussing sexual issues and function. Barriers for discussion and lack of referrals for supportive services in this area may be related to the patient's embarrassment, the clinician's lack of knowledge, or the focus on other issues that may be interpreted as more critical.

The financial burden for patients who undergo HSCT can be overwhelming, including medical expenses for the patient and marrow donor in the case of an allogeneic HSCT, potential travel expenses, and loss of income for other caregiving family members.[25] Patients and their immediate families are often geographically distant from their usual support systems due to the distance from their home to the HSCT center. In some cases, family members who have not been close in the past may be forced to interact with each other, leading to additional stress.

Researchers have described the following factors as predictors of poorer quality of life in patients 1 to 5 years after transplant: diagnoses of anxiety and/or depression, younger age, long-term sequelae, chronic GVHD, unemployment, lower income, poor functional status, family/caregiver distress, and short follow-up by the treatment center.[29,36,37] Psychosocial factors have been shown to directly impact medical outcomes. Patients considered higher psychosocial risk had higher readmission rates 90 days after transplant. Patients who experience depression in the first year also have a higher mortality rate.[38]

The American Society for Blood and Marrow Transplantation (ASBMT) consensus statement recommends annual evaluation of patients' psychological status. Health care providers must have a high level of vigilance to assess depression in both the patient and caregiver years after transplant, with clinical assessments recommended annually after transplant.[39] One study reported that 43% of long-term HSCT survivors with an average of 3.4 years after transplant had clinically significant global psychologic distress.[40] Despite this distress, only 50% of the patients received mental health services.[37] Patients who have undergone HSCT are at a higher risk of PTSD, which has recently been reclassified to include life-threatening medical illness and treatment as qualifying stressors. The prevalence of PTSD in patients who have undergone HSCT is 20% and does not correlate to patient age. PTSD symptoms are similar to patients who do not have cancer, and frequently include nightmares and emotional hypersensitivity.[20]

The concept of posttraumatic growth (PTG) after transplantation has been evolving. By definition, the potential for PTG requires that patients experience a stressful event and then subsequently experience positive psychologic outcomes or benefits. As early as 1996, Fromm identified that positive sequelae are possible after transplantation, including the development of a new philosophy of life, greater appreciation of life,[41] making changes in personal characteristics, and improving relationships with family and friends.[42] Potential predictors of PTG among patients who are post-HSCT include good social support, little avoidant coping, younger age, less education, greater use of positive reinterpretation, problem solving, seeking alternative rewards, more stressful appraisal of the experience, and more negatively biased recall of pretransplant levels of psychologic distress.[17,43] Discussing the PTG potential with patients and making referrals for counseling to experienced clinicians who are aware of the potential for PTG are essential.

Although patients report long-term psychosocial effects after transplantation, they may be reluctant to accept help and fail to access psychological resources and social support.[44] These patients must be encouraged to use resources and seek psychological support because this experience may impair the patients' and families' ability to cope with life after transplant. In an article about HSCT patients' experiences with a support group, Sherman and colleagues identified the themes of meaning and changing of perspectives as patients expressed their struggles with redefining themselves, their priorities, and their values.[25] Some patients wanted to change their former values and behaviors. The support group experience may be therapeutic for patients who often do not have physical signs of transplant to the untrained eye but continue to experience increasing or unresolved psychological and physical issues.[16,24] Sharing a common experience may encourage patients to believe that their symptoms and feelings are not unique and may decrease their feelings of isolation.

Immediate Period Following Diagnosis and Treatment

As the treatment and acute side effects improve and subside, patients often feel that the whirlwind has passed, only to be confronted with an uneasy silence. Weeks and months of clinic and physician appointments, infusions, and admissions stop or trickle to a small stream of appointments. Families who have been functioning on a grinding schedule of crisis mode find the change almost paralyzing. Adding to this halt of activity, health care providers have a tendency to limit their contacts when the patients' physical status has stabilized. This is a critical time when psychosocial interventions and supportive services from other members of the health care team must be instituted for patients and family members to deal with the uncertainty and anxiety of waiting. Fears and anxieties change from fighting the disease to returning to life.[45] Due to the decreased amount of contact with the primary treatment hematologists, patients and families may perceive a withdrawal of support from the medical team. Long-term psychosocial health of the patient and family is affected by the meaning ascribed to the cancer experience, fear of recurrence, support of the family, demographic factors, and financial stressors. This transition time is pivotal for patients' long-term quality of life. Surveillance with specific questions to access the need for referrals can have lasting positive outcomes.

Unlike other patients with cancer, patients with hematologic malignancies who have undergone HSCT are especially vulnerable in the early chronic recovery phase because most patients have to still grapple with integrating into life with some restrictions about activities as their immune system fully recovers. Additionally, some patients still experience anxiety about returning to their baseline level of activity and interacting with their environment due to persistent fear around the higher risk of infection.

Time of Relapse

For many patients, disease relapse represents a more aggressive malignancy than anticipated and can be more threatening and psychologically tasking than the initial diagnosis with cancer.

With the progression of the disease, patients often report upsetting experiences of uncertainty, frequent pain, diminished function, decreased independence, and disability.[46] The medical workup itself can be difficult and anxiety provoking, and psychosocial problems experienced at the time of diagnosis frequently resurface, often with greater intensity.[46] The shock and depression that can accompany disease relapse forces patients and their caregivers to reevaluate the future. In spite of the overwhelming nature of the psychosocial responses, however, most patients cope effectively with disease relapse and intense emotions do not necessarily equate with maladaptive coping.

An essential goal in the psychosocial treatment of patients with advanced cancer is optimal symptom management with robust evidence suggesting symptom management is positively correlated with quality of life.[47,48] However, symptom management can be less prioritized as despairing patients and their families prioritize fighting the disease with aggressive treatment. Patients and families often request participation in experimental protocols, even when there is little likelihood of extending survival. Controversy continues about the efficacy of such therapies and the role health care providers can play in facilitating patients' choices about treatment options. Clear communication about treatment goals and expectations is essential between patients and their care team. Robust evidence suggests that most patients and their families prefer timely and realistic information about their prognosis. However, most patients with aggressive malignancies do not initiate conversations about their treatment intent and end-of-life care goals.[49]

Survivorship

Successful treatment of hematologic malignancies has resulted in a cure for many patients and progressively longer lives for others. Overwhelming evidence from the literature involving survivors with hematologic malignancies suggests that, overall, most do very well after the initial adjustment in the first 1 to 3 years after treatment.[29,50] Although most HSCT survivors express satisfaction with their quality of life, psychosocial challenges certainly exist, and it behooves clinicians to consider these challenges in order to deliver the best care possible and to help patients know what to expect in this phase.[51,52]

The initial transition from patient to survivor can be difficult. Individuals undergoing this transition express common themes in their distress.[53] Fear of recurrence is the most commonly identified concern that colors the transition to survivorship and beyond.[54] It can dominate the lives of both patients and their families and has been shown to be among the strongest predictors of quality of life 1 to 5 years after treatment.[36,47,55-57] Concurrent family dynamics, family stressors, and patient's employment status have also been shown to be strong predictors of quality of life in this period, underscoring the importance of addressing the patient's broader psychosocial context.[58]

Other psychologic challenges of survivorship may include concern over termination of treatment, preoccupation with somatic symptoms, reentry into previous life roles, existential distress pertaining to one's mortality, and difficulties with finances, employment, and insurance. Many patients may be apprehensive about reduced interaction with their clinical team after the constant support they received during chemotherapy and radiation—they may feel suddenly left "on their own" after treatment ends. The nature of social support may also impact patient's perceptions of their anxieties regarding care in the survivorship phase. Patients who have less social support are more likely to feel overwhelmed by the prospect of not having frequent interaction with their clinical teams. Clinicians should proactively discuss these transitions with patients to help patients with realistic expectations of what their needs should be.

Lingering physical symptoms or side effects of treatment may cause further distress as cancer ceases to be the focus of survivors' lives but rather functional limitations that result from the treatment. Acceptance of a new "normal" in terms of level of physical ability and function can be a source of distress—patients should be educated about what to expect as a way to help them adjust to their new "normal." Despite advances in cancer therapeutics, surgical, chemotherapeutic, and radiation therapies can leave permanent damage to organs and physiologic functioning and disfigurement across the different hematologic diagnoses (Table 98.1). Cancer-associated treatments may have resulted in persisting unintended physical side effects such as infertility, treatment-related toxicity, and organ system failure.[47,48,59] In younger cancer survivors, concerns about infertility are particularly distressing and should be addressed adequately.[60] In a study of 250 patients with non-Hodgkin's lymphoma, Hammond and colleagues report that over half of study subjects felt they have not received adequate information about fertility issues, underlying the importance of educating patients regarding what to expect from the sequelae of their treatment.[61]

Psychological distress symptoms persist into short- and long-term survivorship.[50,62–66] As many as 9% to 30% of long-term survivors of hematologic malignancies experience significant symptoms of distress (e.g., anxiety, depression, and PTSD symptoms).[63,65,67] Patient,

disease, and medication factors contribute to the risk of psychiatric comorbidities in patients with hematologic malignancies.[68] Among patient-related factors, age predisposes patients to certain psychiatric illnesses such as delirium—older patients are more at risk compared to younger patients.[69] Women are at increased risk of mood disorders such as depression and anxiety.[70] A history of mental illness also contributes to the risk of developing psychiatric comorbidities.[71] With respect to PTSD in particular, studies have consistently described a higher incidence of this disorder in patients with hematologic malignancies than in the average population.[67] Higher distress levels and avoidance coping styles have been found to be useful predictors of PTSD severity.[17,43,72] Social support impacts various health outcomes such as quality of life and functioning for patients with hematologic malignancies—inadequate social support can also contribute to distress.[73,74] Sociodemographic factors such as lower educational levels and overall lower socioeconomic status result in a greater predisposition to emotional problems.[71]

For disease and treatment factors, a more aggressive hematologic malignancy diagnosis (characterized by biological and genetic markers) and relapsed disease results in a higher risk for psychological distress (especially anxiety) and psychiatric comorbidities.[75] A higher burden of medical comorbidities and complications (e.g., hospitalizations) also results in a higher level of emotional distress.[76-78] With the progression of disease, patients often report distressing experiences of uncertainty, frequent pain, diminished functional ability, increased dependence, and disability.[46] Among patients with hematologic malignancies, those who undergo HSCT, are especially vulnerable to psychiatric comorbidities due to the intense nature of the treatment, prolonged hospitalizations, and potential medical complications (e.g., GVHD) in the short- and long-term recovery from the transplant.[10] Unfortunately, symptoms of distress often go untreated in this population. Hence, routine screening and assessment of psychiatric symptoms in this population are essential to ensuring that patients receive adequate support.

Terminal Stage and End-of-Life Care

Technological advances in health care have improved the potential for a cure of many previously fatal hematologic malignancies. However, many patients still have an incurable disease. When a cure is acknowledged to be impossible and alternative efforts to combat the progression of disease are exhausted, patients are considered terminally ill or dying. While some clinicians advocate for palliative and end-of-life care at this phase of the treatment with the emphasis on forgoing active treatment and emphasizing symptom management,[55,79,80] the paradigm has shifted in the field of palliative care to initiating palliative care alongside curative treatment. In fact, palliative care should be implemented across the illness trajectory—the ultimate goal is to improve the quality of life and facilitate relief of suffering over the course of one's illness.[81] The new World Health Organization definition states: "Palliative care is an approach to care which improves the quality of life of patients and their families facing life-threatening illness, through prevention, assessment, and treatment of pain and other physical, psychologic, and spiritual problems."[82] While evidence supports that palliative care can reduce mortality in addition to improving quality of life, the majority of research is for patients with solid malignancies.[83] Increasingly, research has demonstrated the feasibility, and efficacy of integrating palliative care to improve the quality of life and care of patients with hematologic malignancies and their caregivers.[84]

Despite the high burden of physical and psychological symptoms in patients with hematologic malignancies because of the disease and intensive treatments, there is poor integration of palliative care services in their treatment course. Indeed, as compared with patients with solid malignancies, palliative care clinicians are seldomly consulted for patients with hematologic malignancies.[84] The unmet palliative care needs in this population also extend to survivors who often struggle with post-treatment complications and symptoms of psychological distress which jeopardizes function and quality of life. Evidence supports that illness-specific, cultural, and system-based barriers to optimal end-of-life care and palliative care assimilation exist.[84] Traditionally, patients referred to palliative care are not eligible for curative therapies. Hence, since most patients with hematologic malignancies are candidates for curative therapies such as HSCT or chimeric antigen receptor T-cell (CAR-T) therapy, a clear transition between the curative and palliative phases of treatment is lacking—this ambiguity is a barrier for the timely referral to palliative care.[84] Some of the cultural barriers to palliative care in this population include transplant clinicians' limited knowledge about the benefits of palliative care and their perception that coordination of patient care across all phases of their illness and treatment trajectories should be managed by the oncologist.[85] Overall, the lack of data to support the role of palliative care for this patient population also contributes to transplant clinicians' hesitation to partner with palliative care clinicians for symptom management and end-of-life care conversations. Further, hospice care has not been integrated into the care of patients dying with hematologic malignancies.[86,87] Despite the robust evidence that most terminal patients prefer to spend their final days of life and dying at home, a significant proportion of patients with hematologic malignancies still die in healthcare facilities other than a hospice.[88-90] Respecting patient and family wishes, appropriately managing and alleviating distressing symptoms, and providing care tailored to meeting patients' needs can help patients dying of hematologic malignancies reach the end of life with peace and dignity.

FACTORS THAT INFLUENCE PSYCHOSOCIAL ADJUSTMENT

Psychosocial responses to cancer vary widely and are influenced by several factors that clinicians should bear in mind when considering the responses of individual patients. These factors can be conceptualized as falling into the broad categories of patient, environmental, and disease-related factors.

Patient Factors

Patient demographics, comorbid conditions (including psychiatric disease history), and coping strategies have been consistently documented as important predictors for psychosocial adjustment. Specific personality characteristics, coping strategies, and life experiences also enhance or inhibit positive adjustment to cancer.[91,92] A person's coping style is a useful predictor of adjustment to cancer, as coping style tends to remain stable over time and across situations. Coping strategies and personality attributes can also positively impact long-term survival.[93-95] Active coping strategies including having a "fighting spirit," hopefulness and acceptance of a challenging situation, belief that life has purpose and coherence, and having a feeling of control over events have been positively associated with active participation in treatment and engagement in daily life. By contrast, poor adjustment has been associated with avoidant coping strategies, anxious preoccupation and high distraction, prior negative sexual experiences, body image problems, and inhibition in discussing personal and sexual problems.[96]

Psychologic stability before a diagnosis is a key predictor of psychosocial adjustment to cancer. People with a history of poor psychosocial adjustment before the development of cancer are at the highest risk for psychologic decompensation and should be monitored closely throughout all phases of treatment.[18,97] This is particularly true of people with a history of major psychiatric disorders, psychiatric hospitalization, or both.[18]

Demographics also appear to impact psychosocial adjustment, though the interrelation of individual patient factors can make it difficult to draw conclusions regarding the effect of any specific patient factor on how a given patient will adjust psychosocially to a hematologic malignancy. Nonetheless, demographic factors can significantly impact psychosocial adjustment and should be considered in treatment decision-making.[98,99] In patients diagnosed with hematologic malignancies, female sex and younger age are both associated with worse psychosocial adjustment and poorer quality of life.[16,100-102] This association could at least in part be due to the interrelated factor of anxiety level—females tend to have higher anxiety scores than males. In patients receiving treatment, on the other hand, quality of life seems to be worse with higher age of the recipient at the time of the transplant, poorer self-image, decreased cognitive functioning, and inability to return to work.[103,104]

Finally, smoking status can also impact psychosocial adjustment. One study showed that patients who smoke are at higher risk for psychiatric morbidity, perhaps due to the potential development of depression and/or anxiety with withdrawal symptoms.[105] It is therefore important to include smoking history in the patient's assessment of substance control use when preparing patients for treatment options.

Environmental Factors

Social support contributes significantly to the environment of a patient with cancer. The quality of spousal and familial relationships has a substantial impact on clinical outcomes in the cancer population.[74,106] Social support has consistently been found to influence a person's psychosocial adjustment to cancer.[88,89] Patients who are able to maintain close connections with family and friends during the course of illness are more likely to cope effectively with the disease than those who are not able to maintain such relationships.[86,95,107]

Often the transition out of the hospital post-transplant can be a fearful time for patients and their caregivers. Caregivers frequently serve as the major providers of care outside the hospital, and this can be an overwhelming responsibility.[21] In these situations, referral for home care can provide significant relief of the burden on these family members, in turn helping strained relationships and improving the environmental circumstances for the patient.

Disease-Related Factors

Disease-related factors including the type of disease, side effects of treatment, and residual symptoms all greatly affect psychosocial adjustment. Most disease-related factors are mediated via treatment modalities which introduce varying degrees of side effects, symptoms, and impact on quality of life. Patients who undergo HSCT have a high burden of distress symptoms and adjustment difficulties due to the toxic side-effects of treatment, prolonged hospitalizations, and high risk of life-threatening complications in both acute and long-term recovery. Predictably, HSCT recipients have more psychiatric morbidity if they experience lower functional status and higher regimen-related toxicity.[18] Time interval after treatment is also an important predictor for psychosocial adjustment. Particularly, time since HSCT or completion of treatment appears to be an important factor for facilitating psychosocial adjustment and improving quality of life. In general, during the first year after HSCT, patients perceive their physical and overall well-being as being at its worst, during which time they experience more anxiety and total mood disturbance, as well as report the highest degree of illness intrusiveness in every aspect of life.[29,59,108-112] With the passage of time, improvements in functional status, quality of life, levels of anxiety, depression, and satisfaction with life are often observed.

DIFFERENTIATING PSYCHIATRIC COMPLICATIONS FROM EXPECTED PSYCHOLOGIC RESPONSE

Most patients with hematologic malignancies experience transient symptoms of distress that are responsive to support, reassurance, and information about what to expect regarding the cancer course and its treatment. Living with a chronic illness often requires continuing care and management by a team of specialists. The use of supportive care services has been related to improved quality of life; therefore, it is in the patient's best interest to access services needed for psychologic distress early in the continuum of care.[107] Differentiating a psychiatric complication from expected psychologic responses is imperative. Although the crisis of a cancer diagnosis may result in symptoms of distress, most symptoms do not meet the criteria for a psychiatric disorder. Collaborating with mental health clinicians is essential to the timely diagnosis and treatment of psychiatric comorbidities in this population. Unfortunately, non–mental health providers often miss clinically relevant and severe psychiatric syndromes. Table 98.2 provides a quick reference to common symptoms of distress; also refer to the *Diagnostic and Statistical Manual of Mental Disorders*.

A history of severe mental illness including schizophrenia, bipolar disorder, schizoaffective disorder, and obsessive-compulsive disorder also increases the risk for psychiatric comorbidity in the care continuum. More crucially, cancer mortality is two to four times higher among individuals with mental illness than in the general population.[113] Patients with severe mental illness often report a history of disregard and neglect from providers.[114] Hence, ongoing collaboration between the oncological and psychiatric clinical teams is critical in caring for patients with active psychiatric illness—first to stabilize the psychiatric symptoms and then to treat the cancer.[115,116]

The following guidelines can help identify patients who are especially at risk of developing psychiatric symptoms that require aggressive psychotherapeutic management by a psychiatrist.

1. History of psychiatric hospitalization or significant psychiatric/personality disorder.
2. Persistent refusal, indecisiveness, or noncompliance with regard to needed treatment.
3. Persistent symptoms of anxiety and depression that are unresponsive to usual support from health care providers or family members; symptoms may present in the form of constant fear associated with treatment and procedures or excessive crying and feelings of hopelessness that worsen rather than improve with time.
4. Abrupt, unexplained change in mood or behavior.
5. Insomnia, anorexia, diminished energy out of proportion to expected treatment effects.
6. Persistent suicidal ideation.
7. Unusual or eccentric behavior or confusion (may be indicative of an organic mental disorder).
8. Excessive guilt and self-blame for illness.
9. Evidence of dysfunctional family coping or complex family issues.

TABLE 98.2 Common Psychiatric Disorders

Psychiatric Disorder	Etiology	DSM-5 Criteria
Adjustment Disorder	The development of emotional or behavioral symptoms in response to an identifiable stressor; occurs within 3 months of the stressor and lasts less than 6 months after the stressor has ended; does not represent normal bereavement	1. Marked distress that is in excess of what would be expected for exposure to the stressor 2. Significant impairment in social or occupational functioning
Major Depressive Disorder (MDD)	Symptoms that are present for a 2-week period and a change from previous functioning; symptoms cause clinically significant distress or impairment in functioning; not attributable to the physiological effects of a substance or other medical condition	Five or more of the following in the same 2-week period: 1. Depressed mood most of the day 2. Marked diminished interest or pleasure 3. Significant weight loss or decrease or increase in appetite 4. Insomnia or hypersomnia 5. Psychomotor agitation or retardation 6. Fatigue or loss of energy 7. Feelings of worthlessness or excessive guilt 8. Diminished ability to think or concentrate 9. Recurrent thoughts of death, suicidal ideation, or a plan for suicide
Generalized Anxiety Disorder (GAD)	Excessive worry and anxiety for at least 6 months about a number of activities; the person finds it difficult not to worry; causes impairment in function; not attributable to another mental disorder, substances, or medical condition	Anxiety and worry are associated with three of the six following symptoms: 1. Restlessness 2. Fatigue 3. Difficulty concentrating 4. Irritability 5. Muscle tension 6. Sleep disturbance
Posttraumatic Stress Disorder (PTSD)	Exposure to traumatic events (actual or threatened death, serious injury, violence) with presence of intrusion symptoms associated with the traumatic event; persistent avoidance of stimuli associated with the traumatic events; with significant impairment in function	Experiencing the following symptoms for >1 month after the traumatic event 1. Intrusion symptoms (e.g., nightmares, flashbacks, emotional distress, physical reactivity) 2. Avoidance of trauma-related stimuli 3. Negative thoughts or feelings that began or worsened after the trauma 4. Marked alterations in arousal and reactivity (e.g., irritable behavior, angry outbursts, reckless/self-destructive behavior, exaggerated startle response, sleep disturbance)

SCREENING FOR PSYCHOLOGIC DISTRESS

A number of tools have been developed to screen for psychological distress, but adoption and consistent incorporation into clinical care has been slow.[117,118] The National Comprehensive Cancer Network (NCCN) guidelines have been updated to work towards implementing standard distress screening. These guidelines now clearly advocate for distress to be recognized, monitored, documented, and treated promptly at all stages of disease.[119] In a strong show of support for distress screening, the American College of Surgeons Commission on Cancer has required cancer centers to implement screening programs for psychosocial distress as a criterion for further accreditation.[120]

One tool that is easy to administer and that patients have reported as satisfactorily capturing their problems is the *Distress Thermometer*.[121] The term "*distress*" was selected as it was felt to be more acceptable and less stigmatizing than other related terms (e.g., psychiatric, psychosocial, emotional). The tool, which consists of two parts, is similar to pain measurement scales that ask patients to rate their pain on a scale from 0 to 10. The first part is a picture of a thermometer, upon which patients are asked to mark their level of distress. A rating of 4 or above indicates that a patient has symptoms indicating a need for evaluation by a mental health professional and potential referral for support services. On the second part, the patient marks items that relate to his or her distress from a six-item problem list (Fig. 98.2).[121,122] Multiple studies have validated the use of this distress thermometer in various oncologic settings including HSCT, and it has been found to be a useful tool for screening HSCT recipients before their transplant hospitalization.[123,124] Pre-transplant distress appears to be highly predictive of distress following transplant, though controversy remains as to whether screening for pre-transplant distress and structuring care accordingly makes a difference in post-transplant distress.[125]

A diagnosis of major depression in medically ill patients relies heavily on the presence of affective symptoms such as hopelessness, crying spells, and guilt; preoccupation with death or suicide; feelings of diminished self-worth; and loss of pleasure in most activities, such as being with friends and loved ones. The neurovegetative symptoms that usually characterize depression in physically healthy individuals are not good predictors of depression in the medically ill because disease and treatment can also result in similar symptoms. Additionally, patients who are at risk for suicide become more energized after

immediate treatment and appear to look better long before their depressive feelings and suicidal thoughts are relieved. Hence, careful monitoring of suicidal ideation should continue for weeks after the patient appears improved.

SCREENING FOR POSITIVE PSYCHOLOGICAL WELLBEING

Although most of the emphasis on achieving psychological health among cancer patients has focused on distress and the alleviation of distress, positive psychological factors such as optimism, gratitude, and meaning also significantly contribute to the psychological wellbeing in patients with serious illnesses. Indeed, the presence of positive psychological wellbeing constructs is not merely the opposite of distress. Optimism and depression, for example, are only modestly inversely correlated—and strong evidence suggests that the beneficial effects of positive psychological wellbeing on clinical outcomes exceed the adverse effects of negative psychological syndromes like depression.[126-128] Hence, it is imperative for positive psychological wellbeing factors to be explored and promoted when assessing for the psychological wellbeing of patients with hematologic malignancies.

MANAGEMENT OF PSYCHOSOCIAL PROBLEMS

Pharmacological and non-pharmacological interventions have both been successfully used to manage distress in patients with hematologic disorders. Because of the increasing complexity of patient care, a multidisciplinary approach is imperative. Psychologic distress that can be managed effectively includes anxiety and depression, sexual dysfunction, body image disturbances, noncompliance, pain, neurologic complications such as delirium and dementia induced by brain metastasis or treatment, anticipatory and posttreatment nausea and vomiting, anorexia and feeding problems, and marital and family difficulties.

Pharmacologic Interventions

Different psychotherapeutic agents (including antidepressants, antipsychotics, and anxiolytics) effectively manage psychiatric symptoms (e.g., anxiety, depression, delirium) in patients with hematologic malignancy.[129] Consideration of drug-drug reactions, physical symptom burden and toxic side effects (especially those pertaining to the bone marrow environment for HSCT recipients), and overall medical comorbidities is essential to the selection of pharmacological agents.[31]

Antidepressants from various classes such as selective serotonin reuptake inhibitors (SSRIs) or selective norepinephrine reuptake inhibitors (SNRIs) can effectively manage symptoms of depression and anxiety. SSRIs and SNRIs, however, can reduce platelet serotonin resulting in platelet dysfunction and increased risk of bruising and bleeding, especially for patients with hematologic disorders.[130] As such, fluoxetine, paroxetine, and sertraline should be used with caution since they have the highest degree of serotonin reuptake inhibition and are more frequently associated with bleeding problems.[10,131] Mirtazapine, an atypical antidepressant used primarily to treat depression, can also be an effective anxiolytic, sedative, antiemetic, and appetite stimulant. However, on rare occasions, mirtazapine can cause neutropenia and agranulocytosis.[132,133] Though antidepressants are the gold standard for managing anxiety as a whole, benzodiazepines can effectively manage acute or intermittent anxiety that may arise at different stages of the care continuum. Benzodiazepines rarely cause agranulocytosis but clonazepam and diazepam have been associated with thrombocytopenia, anemia, and leukopenia.[134]

Antipsychotic medications effectively treat neuropsychiatric and behavioral concerns that accompany delirium, the sudden change in mental status characterized by disorientation, and different psychiatric symptoms including psychosis. Antipsychotics also have anxiolytic (e.g., quetiapine, olanzapine, haloperidol), antiemetic (e.g., olanzapine), appetite stimulation (e.g., olanzapine), and sedative properties. However, several antipsychotic medications including olanzapine, clozapine, chlorpromazine, and haloperidol should be used cautiously in patients with hematological disorders due to their associations with agranulocytosis and neutropenia.[10,134-136] Mood stabilizers and antiepileptics (e.g., valproic acid) used for patients with comorbid psychiatric disorders such as bipolar disorder can also be used to manage agitation in patients with delirium whose medical problems prohibit the use of antipsychotic medications.[137]

Patients must be monitored closely by a consistent provider during the initiation and modification of psychopharmacologic regimens. In patients with a limited prognosis shorter than a few weeks, recent evidence suggests that ketamine may be useful for the rapid treatment of depression. The average time-to-response is on the order of a few hours.[138] It is important to note that although sadness may be present in the end-of-life period, major depression is not common and should be addressed. It is beyond the scope of this chapter to provide a comprehensive overview of all psychopharmacological agents—the threshold to collaborate with psychiatric providers in the management of these symptoms is crucial. A comprehensive discussion of psychotropic drugs is summarized in the quick pocketbook reference for oncology clinicians.[139]

Psychotherapeutic Interventions

"Returning to normal" is a prominent theme and desired goal but is not always possible for patients with hematologic malignancies.[109,140] Survivors of cancer continue to face challenges with long-term physical and psychologic symptoms long after treatment has ended, and data indicate that they report more contact with mental health providers than do people without cancer.[141] The ASBMT released a joint statement recommending screening and preventive practices for long-term survivors of HSCT. The recommendation states that "a high level of vigilance for psychologic symptoms should be maintained. Clinical assessment is recommended throughout the recovery period, at six months, one year, and annually thereafter, with mental health professional counseling recommended for those with recognized deficits."[39] The number of intervention studies designed with the hematologic population is limited; however, growing interest in survivorship is changing the research climate in this area. Psychological interventions should be tailored to a patient's need—it may take the form of group therapy, individual psychotherapy, family therapy, marital therapy, cognitive or behaviorally-oriented therapy, or some combination.[142]

Support groups can provide a therapeutic experience for patients and their caregivers. Social support has been associated with a variety of important patient-reported outcomes including quality of life.[74] Patients often feel alone in their distress and report that sharing a common experience normalizes their feelings, provides an avenue for emotional support, facilitates dialogue to problem solve, and offers opportunities to learn from other patients. Support groups facilitated by professionals such as social workers, nurses, or psychologists can provide a forum for health and psychological education and provide patients with printed literature and online community-based resources. Sherman and colleagues found that psychoeducational support groups facilitated by professionals were a helpful strategy for psychologic recovery in patients' post-HSCT course.[25]

Other modalities have been shown to be effective with patients.[91,109] Studies have consistently shown that relaxation training with or without guided imagery or hypnosis is associated with better quality of life, improved symptom management, and decreased symptoms of anxiety and depression.[140,143,144] Although relaxation training is not time consuming, it requires patients to be motivated to learn and practice new techniques as a way of coping. Cognitive therapy/reappraisal, problem solving, and stress management training are also helpful in the general cancer population.[140,145,146] Fritzsche and colleagues identified that a considerable need for the psychotherapeutic treatment of hospitalized patients with hematologic malignancies is best handled by mental health professionals.[143] They described a consultation-liaison (CL) psychiatry service that provides psychosocial support for patients with hematologic malignancies, including patients going through transplant. The service screened patients for anxiety, depression, poor coping, quality of life, and psychosocial openness for support, and provided psychotherapy, relaxation training, or group therapy as interventions. Although all transplant patients received support from the team, 23% of the hematology patients on the general ward received additional psychosocial interventions. There is also increasing evidence for integrated palliative care services in the care of patients with hematologic malignancies. In a randomized clinical trial of 160 adults with acute myeloid leukemia, El-Jawahri and colleagues showed that integrated palliative care improved patient-reported quality of life, as well as depression, anxiety, and posttraumatic stress symptoms during intensive chemotherapy and for up to 24 weeks.[147] Also, among patients who died, patients who received integrated palliative care were more likely to have reported discussing their end-of-life care preferences and less likely to have received chemotherapy near the end of life.

Other evidence-based interventions found to be helpful in the general oncology population include individual and group counseling, family therapy, and music and art therapy. It has been estimated that one of six cancer survivors with mental health problems is unable to access mental health services due to economic constraints and high cost.[141] If cost is prohibitive and referral to a psychologist or psychiatrist is not feasible, both patients and providers must investigate other potential providers, such as chaplains, art therapists, music therapists, social workers, and psychiatric advanced practice nurses who may be more affordable. Other possibilities include online support groups and advocacy organizations, including local wellness communities, although data on their impact on alleviating symptoms of distress is limited.

Increasing evidence supports the use of an aerobic exercise program for patients with hematologic malignancies.[148-150] Researchers have concluded that fatigue and loss of physical performance in patients undergoing HSCT may improve with exercise.[149] Others have found increased muscle strength with supervised weight bearing and lifting after allogeneic HSCT.[148] Table 98.3 outlines the major psychotherapeutic modalities and their advantages, goals, and indications.

FUTURE DIRECTIONS

The psychosocial issues faced by patients with hematologic malignancies are influenced by individual, environmental, and disease-related factors. Most patients undergoing cancer treatment, as well as their caregivers, experience expected periods of psychologic turmoil that occur at transition points along the clinical course of cancer. In a small

TABLE 98.3 Non-Pharmacological Interventions Successfully Used for Patients and Caregivers with Hematologic Malignancies

Modality	Selected Indications	Goals and Advantages	Comments
Individual Psychotherapy	Prolonged adverse reactions to diagnosis, treatment, and other aspects of chronic illness (e.g., anxiety, depression)	Supports patients and enhances the ability to cope with distressing feelings Short-term therapy; focused and goal directed	Pharmacology and family involvement are useful adjuncts in some cases
Support Groups	Patients who desire contact with others who are experiencing chronic illness	Supports patient and enhances coping ability Patients benefit by observing coping strategies of others Usually does not involve a fee	Expands social network of patients with limited support systems
Family and Marital Therapy	Relationship problems secondary to illness (e.g., family tension, role changes, conflict, sexual problems)	Assists couples with clarifying problems and facilitates solving them together Addresses role changes in the family system	Problems, issues, and concerns about relationships including children can be addressed
Mind-body Therapies (e.g., progressive muscle relaxation, yoga, guided imagery, Reiki, meditation, hypnosis, and biofeedback)	Patients who desire assistance with control of pain, anxiety, anticipatory and posttreatment nausea and vomiting, fears associated with medical procedures	Increases sense of control and participation in treatment Individualized to meet patients' preferences and circumstances Time limited and goal directed Evaluated in terms of observable changes in symptoms and self-efficacy	Realistic goals should be stated explicitly (Some patients may view these therapies as curative for cancer)

proportion of patients, more severe psychiatric complications may occur, warranting a referral to a psychiatric specialist, including psychiatrists, social workers, psychologists, and psychiatric nurses. Screening for ongoing psychiatric problems must become standard of care. A variety of psychotherapeutic interventions are useful for helping patients work through the psychological challenges that may accompany their diagnosis and treatment.[6] Supportive psychotherapeutic measures should be used routinely because they minimize distress and enhance feelings of control and mastery over self and environment.

Throughout the clinical course of cancer, the patient's relationship with health care providers and the presence of supportive social networks are essential to ensuring successful management of the many physical and psychosocial demands imposed by a cancer diagnosis and treatment. As scientific inquiry continues to produce vast but sometimes conflicting information regarding etiology and treatment of cancers, concurrent research regarding the psychosocial aspects of hematologic malignancies is needed to ensure that patients with hematologic malignancy and their caregivers have optimal psychological wellbeing as they navigate their cancer diagnosis and treatment as well as in survivorship. Robust studies on the psychosocial aspects of cancer may provide some "missing links" regarding psychosocial adaptation and patient-reported outcomes in the immediate and long-term recovery from treatment. The Institute of Medicine report that recommends that all cancer care should ensure the provision of appropriate psychosocial health services states that at a minimum, patients must be screened for emotional distress and evaluated for additional services.

CHAPTER 99

PAIN MANAGEMENT AND ANTIEMETIC THERAPY IN HEMATOLOGIC DISORDERS

Thomas W. LeBlanc

Relieving pain in patients with hematologic disorders requires a multifaceted approach.[1,2] This chapter will provide the clinician with the tools to perform a systematic evaluation of the pain complaint and propose a rational, evidence-based, strategy. After the source and type of the pain has been identified and assessed, appropriate nonpharmacologic and pharmacologic therapies can be initiated. The approach to managing pain in hematologic disorders is largely based on the approach for managing cancer-related pain. We do not address the neurosurgical or anesthetic procedures for managing pain; those interested in these techniques are referred to several excellent reviews.[1–5] We will also review the pharmacologic strategies for managing nausea in patients with hematologic disorders undergoing treatment.

TAXONOMY OF PAIN

Although there is no one standardized classification system for cancer pain, several systems have been proposed. Cancer pain syndromes, and thus by analogy, pain syndromes in hematologic disorders, may be classified temporally, pathophysiologically, and etiologically, according to distinct clinical–anatomical entities, or any combination thereof. It is important to determine both the etiology and inferred pathophysiology in the assessment of the pain complaint because this may suggest the use of specific therapies. Pain can be categorized as *nociceptive* (somatic or visceral), *neuropathic*, or *idiopathic*.[6] Nociceptive pain is pain that is sustained predominantly by tissue injury or inflammation. Nociceptive somatic pain is described as sharp, aching, stabbing, throbbing, or pressure-like. Nociceptive visceral pain is poorly localized and is usually described as crampy pain (e.g., obstruction of hollow viscus) or as aching and stabbing (e.g., pain secondary to splenomegaly). Neuropathic pain is sustained by abnormal somatosensory processing in the peripheral or central nervous system (CNS). Sensations described as “burning,” “shock-like,” and “electrical” typically suggest neuropathic pain. On physical examination, patients may have allodynia (pain induced by nonpainful stimuli) and hyperalgesia (increased perception of painful stimuli). In the absence of evidence sufficient to label pain as either nociceptive or neuropathic, we may use the term *idiopathic*. However, in patients with hematologic disorders, this term should lead to additional workup and a search for an underlying etiology and pathophysiology.

EVALUATION OF THE PAIN COMPLAINT

Initial Evaluation

Effective pain management requires a comprehensive assessment of the patient’s pain. The clinical presentation of a patient with chronic pain is very different from that of a patient in acute pain. The patient with chronic pain does not present with the common autonomic manifestations of acute pain (e.g., tachycardia, sweating, elevated blood pressure) or facial grimacing, but often appears withdrawn, quiet, depressed, or irritable; moves very little spontaneously; and experiences discomfort when moved. When the pain is relieved, these patients often exhibit completely different behaviors, becoming mobile, engaged, and involved with other people. The first component in the assessment is to believe the patient’s complaint.

Patient reports of pain are valid, reliable, and reproducible.[1] A variety of assessment tools are available, and most can be completed in 5 to 10 minutes or less.[1,2] A commonly-used example is the “Brief Pain Inventory.”[3] The pain complaint should be characterized by a number of descriptors, including the pain location, intensity, quality, onset, and duration; location and patterns of radiation; and what relieves or exacerbates the pain and its functional consequences (including how the pain affects the patient’s function, including their ability to sleep or eat and how it affects physical activity, relationships with others, emotions, and concentration). Most patients with chronic cancer pain also experience periodic flares of pain, or “breakthrough pain.”[2,4] An important subtype of breakthrough pain is “incident pain,” which is caused by voluntary activity. The initial evaluation should determine the extent to which the patient has breakthrough pain and if it is provoked by movement (nociceptive) or tends to be paroxysmal in nature (neuropathic). This subjective information, combined with the physical examination and diagnostic studies, may identify a specific pain syndrome and its implied pathophysiology.

In a patient with a hematologic disorder, the cause of pain may be the disease itself, the specific therapy for the disease, diagnostic procedures related to the disease, or unrelated disorders (Table 99.1). Splenomegaly, bone injury (e.g., infarction, infection, hemarthroses, and infiltration), leptomeningeal infiltration, and spinal cord compression frequently accompany hematologic diseases. Chemotherapy and radiation therapy can cause mucositis, typhlitis, hemorrhagic cystitis, and peripheral neuropathy; corticosteroid withdrawal may cause myalgias. Immunosuppression, caused by the diseases themselves or by the therapies used to treat them, may lead to painful infections such as perirectal abscesses, herpetic or candidal esophagitis, and herpes zoster. Patients with sickle cell disease have a number of causes for both acute and chronic pain (Table 99.2).

Distress, however, may arise from nonanatomic sources. The pain complaint may represent the patient’s only means of expressing nonspecific feelings of distress to the clinician. Chapman recognized three categories of this distress: anxiety, arising from fear of disfigurement or of uncontrollable pain, fear of loss of social position or of self-control, or fear of death; anger at the failure of the physicians to provide a cure; and depression from the loss of physical ability, a sense of helplessness, and the impact of financial problems. In addition to these psychological, social, and financial contributions, spiritual concerns may exacerbate any concomitant painful sensations.[5] Alleviating them may significantly reduce distress and decrease the need for pain medications or other interventions.

Sometimes there may be a disparity between the patient’s expression of pain and the patient’s family or friends’ appreciation of the impact of the pain. The following script may help to begin a conversation around this issue: “You seem to show a different perspective about the pain from those of your family and friends. Help me to understand *what the pain is like for you* and why you think your family and friends feel differently.” Differences in cultural backgrounds may also affect the expression of pain, and thus may vary within a family as well as in different families.[5]

TABLE 99.1 Common Pain Syndromes in Hematologic Malignancies

Procedure-Related Pain	
Deep somatic pain	Bone marrow aspiration, biopsy, and harvest
	Headache following lumbar puncture
Superficial somatic pain	Venipuncture (needle insertions)
	Central catheter placement/positioning
Therapy-Related Pain	
Deep somatic pain	Bone marrow expansion and/or sensitization by granulocyte colony-stimulating factor, osteoporosis (e.g., from corticosteroids use), myalgias (e.g., from corticosteroid withdrawal), myopathy
Superficial somatic pain	Oropharyngeal mucositis (e.g., from chemotherapy or radiotherapy)
Visceral pain	Enteritis, typhlitis, hemorrhagic cystitis
Neuropathic pain	Drug-related neuropathies (e.g., from chemotherapy agents)
Headache	Drug-related (e.g., due to tretinoin)
Pain From Hematologic Malignancy	
Somatic pain	Bone infarct or necrosis, osteomyelitis, compression fracture, hemarthrosis
Visceral pain	Tumor involvement, splenomegaly, lymphadenopathy or lymphadenitis
Neuropathic pain	Paraproteins with antimyelin properties, amyloid infiltration, peripheral nerve compression, spinal cord compression
Mixed pain	Headache, meningeal infiltration or infection, brain metastasis, or primary tumor

TABLE 99.2 Classification of Pain Syndromes in Sickle Cell Disease

- Pain secondary to the disease itself
  - Acute pain syndromes
    - Acute chest syndrome
    - Calculus cholecystitis (pigment stones)
    - Hand–foot syndrome (in children)
    - Hepatic crisis
    - Priapism
    - Pulmonary infarction
    - Recurrent acute painful episode
    - Splenic sequestration (in children)
  - Chronic pain syndromes
    - Arthropathies or arthritis
      - Avascular necrosis
      - Chronic osteomyelitis
      - Intractable chronic pain
      - Leg ulcers
    - Neuropathic pain
    - Pain secondary to therapy
    - Loose prosthesis (in patients after arthroplasty for avascular necrosis)
    - Opioid withdrawal
  - Postoperative pain
- Pain caused by comorbid conditions

From Ballas SK. Pain management of sickle cell disease. *Hematol Oncol Clin North Am.* 2005;19:785.

Continued Assessment

A standardized measurement tool, such as a verbal rating scale (VRS) or a visual analog scale (VAS), should be consistently used during follow-up visits.[1,2,6] These measurements are thought to be more accurate than mere qualitative descriptors, such as: "The pain is better." Using, for example, a scale of 0 (no pain) to 10 (the worst pain one can imagine), a decrease in pain intensity from 10 to 8 indicates that the patient could benefit from additional dose titration, but a decrease from 10 to 3 suggests that the current dose is effective. A pain goal should be assessed by asking the patient, "What level of pain would be acceptable to you?" Negotiating this goal together is often necessary, and helpful, as the complete elimination of pain is often not possible. The ongoing assessment should also pay attention to changes in the phenomenology of the pain, new occurrences of pain, or a change in the location of pain—all of which may suggest progression of disease in the patient with a hematologic disorder.

The successful outcome of pain therapy should be more than simply the lowering of pain intensity scores, but the impact on function, the minimization of side effects from treatment, and the prevention of opioid misuse. Passik and Weinreb developed a useful mnemonic device for the assessment of pain therapy in chronic nonmalignant pain known as the "4 As": analgesia, activities of daily living, adverse events, and aberrant drug-taking behaviors (e.g., repeated dose escalation or nonadherence, hoarding medications, or acquiring controlled substances from other medical sources or even non-medical avenues).[7] By focusing on these relevant domains in the continued assessment of the pain therapy, the clinician is able to determine if the therapy makes a true difference in the patient's life, stabilizes or improves psychosocial functioning, manages side effects, and provides a means of assessing for aberrant behaviors. Ultimately, the goal should be to lower the pain *to a level acceptable to the patient* and to improve the patient's level of functioning.

THERAPY DIRECTED AT THE UNDERLYING ETIOLOGY

A major component of pain therapy is to ameliorate the underlying cause of the pain, when possible. Surgery, chemotherapy, radiation therapy, immunosuppression, and antibiotics may all be used. Attention to patient comfort should be maintained regardless of the diagnostic or treatment interventions proposed. Generally speaking, the most effective pain management strategy for cancer-related pain is to effectively treat the cancer. This is not always possible, unfortunately.

NONPHARMACOLOGIC METHODS OF PAIN MANAGEMENT

Cognitive-Behavioral Interventions

Education and Reassurance

Patients with serious hematologic disorders are often required to undergo extensive diagnostic testing, which can include painful procedures. A rehearsal of the planned test or procedure, including a discussion (or view) of the appearance of the room and the length of time to be spent in the test apparatus, can minimize the patient's anxiety. Such explanations, offered preoperatively, lessen the need for postoperative medication and shorten the patient's hospital stay. If conscious sedation is not planned, a pleasant distraction may be helpful to divert attention from certain procedures (e.g., bone marrow aspiration or biopsy) that take place in the clinician's office or in the patient's room. For example, a clinician might present a patient with an electronic tablet–guided relaxation training session while the physician is preparing for a procedure. The patient can utilize the relaxation techniques recently acquired during the procedure in order to diminish pain.[8]

Hypnosis

Hypnosis can be a useful adjunct in the management of pain, including for patients undergoing painful procedures.[5] The hypnotic trance, a state of heightened and focused concentration, allows one to manipulate the perception of pain and diminish sleeplessness, anxiety, and anticipation of discomfort. Hypnotic training of patients with sickle cell disease or hemophilia decreases the frequency and pain intensity of painful crises or bleeding episodes, respectively. In a controlled trial comparing hypnosis with cognitive-behavioral therapy in relieving mucositis after a bone marrow transplant, patients using hypnosis reported a significant reduction in pain control compared with patients who used cognitive-behavioral techniques.[8]

In the absence of a formal hypnotic induction, words used by a practitioner to describe procedures are very important. For example, suggesting that the numbness and coolness of a local anesthetic will persist may diminish the discomfort of a bone marrow biopsy. Using the phrase: "You will feel something; I'm not sure what you will feel because everyone feels this a little differently" in place of "This is going to hurt a lot!" gives the patient permission to alter the sensation and may also diminish the experience of pain.[9]

Meditation

Meditation has long been used as a method for controlling pain. Given the wide range of meditation practices and methods, it has historically been difficult to conduct evidence-based research into the effectiveness of meditation. Some research has shown that using meditation to increase focus and clarity does improve pain symptoms and appears to correlate with decreased pharmacologic requirements.[10]

Cognitive-Behavioral Techniques and Counseling

The cognitive-behavioral approach addresses several psychosocial and behavioral factors that contribute to patients' experience of pain.[2,4,8] These techniques have demonstrated clinical utility for patients with a wide range of chronic pain syndromes. Psychological counseling as part of a multidisciplinary approach to pain treatment provides education, support, and skill development for patients with pain. It can improve patients' abilities to communicate their pain to health care personnel and may be effective in overcoming anxiety and depression. Spiritual counseling may help patients who have lost hope, can find no meaning in their lives, or believe they are being punished or have been forsaken by God.[5] They may interpret their pain in light of these feelings. Through counseling, they can regain a sense of worth and belonging. As they recast the pain in its true light, its intensity is often diminished.

Cutaneous Techniques

Acupuncture, massage, vibration, and applying cold or heat to the skin over injured areas are often very effective. Cold wraps, ice packs, or cold massage using a cup filled with water that has frozen into a solid piece of ice relieve the pain of muscles that are in spasm from nerve injury. Heat from heating pads, hot wraps, or paraffin treatments can soothe injured joints but should not be used over areas of vascular insufficiency.

EMLA, a cream containing two topical anesthetics (2.5% lidocaine and 2.5% prilocaine) is used, especially in children, to decrease the pain of superficial cutaneous procedures (e.g., venous cannulation or skin anesthesia before lumbar puncture, bone marrow aspiration, or biopsy).[5] In adults, it is sometimes used before access of implanted vascular access devices or CNS ports. To achieve anesthesia, the EMLA cream must be applied 1 to 1.5 hours before the planned procedure in a mound under a semipermeable dressing such as Opsite or Tegaderm. When EMLA is used as directed, methemoglobinemia has not been a problem even in infants as young as 3 months old. Skin blanching occurs, sometimes exceeding or equaling the frequency of that found with placebo moisturizing cream placed under the occlusive dressing. ELA-Max, a cream containing 4% lidocaine, is available over the counter and is an alternative to EMLA cream. Because it does not contain prilocaine, there is no risk of methemoglobinemia.

Lidocaine patches can be used over areas of hyperesthesia, as can occur in patients with postherpetic neuralgia (PHN) or nerve entrapment by vertebral body collapse.[5] The patch is applied to the affected area for no more than 12 consecutive hours a day and can be cut to size. Use should be avoided over areas of broken skin and in patients undergoing radiation therapy. Lidocaine patches have been safely applied for up to 24 hours/day for up to 4 days with minimal systemic absorption in healthy volunteers and in patients with PHN.

Neuromodulation

Transcutaneous electrical nerve stimulation (TENS) devices are indicated for patients with dermatomal pain, such as PHN or radiculopathy from spinal cord compression.[5,11] For optimal effect, a physiatrist or physical therapist familiar with the device should train the patient in its use. The efficacy of TENS therapy for patients with cancer pain remains controversial.

Radiation Therapy

Radiation therapy is commonly used in the management of painful bone lesions, spinal cord compression, bulky lymphadenopathy, and symptomatic splenomegaly in patients with hematologic malignancies.[5,12] Radiotherapy is the treatment of choice for local metastatic bone pain in most situations, although patients with underlying pathologic fractures may require surgical fixation before radiotherapy. Randomized trials have shown that single-fraction radiotherapy is as effective as multifraction radiotherapy in relieving pain caused by metastases. However, there are higher rates of retreatment, and single-fraction radiotherapy may not prevent pathological fractures or spinal cord compression.[12] In patients with poor performance status or a short life expectancy, a single dose (8 Gy) of radiation or a hypofractionated course (20 Gy/5 fractions) may be preferable and less burdensome. Some hematologic malignancies can be more sensitive to radiation therapy than are most solid organ tumors, with effective palliation of cancer-related symptoms occurring at lower radiation doses in many cases of lymphoma, for example.

Vertebroplasty and Kyphoplasty

Vertebroplasty and kyphoplasty are both minimally invasive techniques used to stabilize vertebral compression fractures and reduce pain. Vertebroplasty is a procedure in which bone cement, usually polymethylmethacrylate, is injected into the vertebral body. With kyphoplasty, a balloon is first inserted into the vertebral body followed by inflation and then deflation before cement is added. Balloon kyphoplasty has been shown to stabilize pathologic vertebral fractures caused by multiple myeloma and significantly reduce pain, though there remains some debate about its efficacy amid other negative studies.[13]

Anesthetic Techniques

Trigger-point injections, nerve blocks, and neurolytic procedures are useful for acute and chronic localized pain. After excisional biopsy of an axillary lymph node, for example, a burning, constricting pain in the posterior arm and chest wall may develop; this pain is often promptly relieved by trigger-point injection.

Lymphoma or multiple myeloma may involve the spine and lead to vertebral collapse or pain from progressive disease that is refractory to antineoplastic therapy. Such pain is often particularly difficult to manage. Insertion of temporary or permanent indwelling epidural or intrathecal catheters to deliver opioids, local anesthetic agents, clonidine, or combinations of these and other agents can be very effective, especially in relieving lower thoracic or lumbar spine pain, as well as pelvic and lower extremity pain.[14] Reviews of the indications for and techniques of the anesthetic and neurolytic procedures are available.[15] Consultation with an expert in anesthesiology and/or palliative medicine can be helpful in these situations, to obtain expert guidance about appropriate indications for these procedures.

PHARMACOTHERAPY

Drugs useful for pain relief include nonopioid analgesics, opioids, and adjuvant analgesics. Most patients require a combination of medications for optimal pain relief (Fig. 99.1).[16]

Management of Mild-to-Moderate Pain

Nonopioid analgesics should be given to patients with mild-to-moderate pain.[1,2] Aspirin and nonsteroidal antiinflammatory drugs (NSAIDs), including cyclooxygenase-2 (COX-2) inhibitors, are especially useful as antiinflammatory agents because they decrease local prostaglandin release through the inhibition of COX (although the mechanisms for their analgesic properties are not as clear).[17] Acetaminophen is an effective analgesic but only a weak antiinflammatory agent. Daily intake of acetaminophen should not exceed 3 to 4 g because of the potential hepatic toxicity. It is important to prescribe an adequate dose of acetaminophen or NSAID at regular intervals, switching to another nonopioid analgesic only when maximal doses of the first have become ineffective.[17]

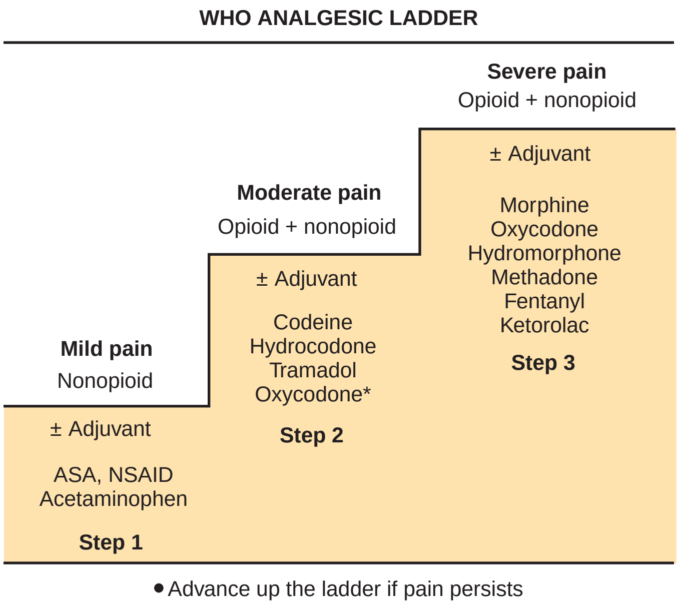

Figure 99.1 STRATEGY FOR PHARMACOLOGIC MANAGEMENT OF PAIN USING A MODIFIED (FOUR-STEP) WORLD HEALTH ORGANIZATION ANALGESIC LADDER. Multiagent therapy is usually required for optimal pain management. Patients with mild pain should be started on a nonopioid analgesic, and those with moderate pain should be started on a step 2 opioid. Many patients can benefit from the addition of a nonopioid to the opioid (e.g., for bone pain) or an adjuvant agent to the opioid (e.g., for neuropathic pain). If this combination does not produce adequate relief or the patient presents with severe pain, step 3 opioids should be begun initially. Toradol (Ketorolac) is a nonsteroidal antiinflammatory drug (NSAID) with the pain-relieving potency of a step 3 opioid. Many patients can benefit from the addition of nonopioid analgesics or adjuvants, if indicated. *Oxycodone in combination with products. It has been suggested that if opioids with nonopioid analgesics and adjuvants is unsuccessful in providing relief that an additional "4th step" of interventional/intraspinal delivery systems should be initiated.[16] *ASA*, Aspirin; *NSAID*, nonsteroidal antiinflammatory drug; *WHO*, World Health Organisation.

Ketorolac tromethamine (Toradol) is an NSAID of particular value in relieving moderate-to-severe acute pain.[18] A parenteral dose of 30 mg of ketorolac equals the pain-relieving potency of a parenteral dose of 15 mg of morphine, and acute toxicity is minimal if the total daily dose is under 100 mg. Oral ketorolac is considered less potent. Ketorolac has all of the side effects of the NSAIDs and is not recommended for use beyond 5 days because of an increased risk of renal toxicity. If that degree of pain relief is needed chronically, an opioid agent should be substituted.

Because NSAIDs can cause renal insufficiency in a significant number of patients, renal function should be assessed 1 to 2 weeks after initiation of any of these agents. NSAIDs should be used with caution in patients with a history of aspirin allergy or asthma because they can precipitate bronchospasm in as many as 20%. Significant edema can occur in patients with cirrhosis or congestive heart failure.[17] The relatively selective COX-2 inhibitors, such as meloxicam, celecoxib, and nabumetone, have been shown to cause similar gastrointestinal side effects as nonselective NSAIDs.[19] If NSAIDs are required in patients with a history of significant gastritis or ulcer disease, or who are older than 70 years, COX-2 inhibitors or a concomitant proton pump inhibitor should be considered. Cardiotoxicity is well described in the literature for COX-2 selective inhibitors.[20] Recently, the cardiac risk associated with traditional NSAIDs has been questioned. In a meta-analysis that included naproxen, ibuprofen, diclofenac, and several COX-2–specific inhibitors, ibuprofen and diclofenac demonstrated an increased risk of stroke. Diclofenac was also associated with an increased risk of cardiovascular death. Naproxen was not noted to increase risk in this study.[20] Nonopioid analgesics should be continued when opioid analgesics are added because they can potentiate the pain-relieving effect of the opioid (see Fig. 99.1).[21] However, when aspirin or acetaminophen is included in a fixed drug combination (e.g., Percodan, Percocet), toxicities may develop if the patient uses the medication more frequently than prescribed. The metabolism of salicylates is limited by the capacity of the hepatic microsomal system.[5] After it is saturated, salicylate levels are dependent on renal clearance. Small increases in maintenance doses can lead to serious salicylism. Patients with low albumin levels or acid urine are particularly susceptible to the development of salicylate toxicity.

Tramadol, which both weakly inhibits norepinephrine and serotonin reuptake, and weakly binds to μ-opioid receptors and has opioid-like side effects, can be used for mild-to-moderate pain. A dose of 100 mg is more effective than 60 mg of codeine. Tapentadol (Nucynta) also has both μ-receptor agonism and norepinephrine reuptake inhibition. Studied in moderate-to-severe acute postoperative pain, osteoarthritis, and low back pain, doses of 50 to 100 mg every 4 to 6 hours are comparable to oxycodone 10 to 15 mg every 4 to 6 hours with less nausea, vomiting, and constipation.

Management of Moderate-to-Severe Pain

Opioid therapy is the cornerstone of management of patients with moderate-to-severe pain.

In patients with acute moderate-to-severe pain (i.e., ≥4/10 on VRS), intravenous dosing should be started with the goal of rapid titration (see, for example, National Comprehensive Cancer Network [NCCN] guidelines for Adult Cancer Pain).[22] In opioid-naïve patients, morphine 2 to 5 mg or its equivalent (see box on Relative Potencies of Commonly Used Opioids) should be dosed every 15 minutes (peak effect ~15 minutes). The patient should be reassessed for analgesic effect and side effects. If pain is not relieved, then the dose can be increased by 50% to 100%; if the pain score decreases to an acceptable level, then the same dose can be continued and given as a standing dose "around the clock." Alternatively, a patient-controlled analgesia (PCA) can also be used in these situations and can provide the patient with significant control over their pain experience. Similarly, the PCA demand dose can be calculated over a 24-hour period to determine the "basal dose" of opioid the patient will need for stable analgesia. This can be provided as a basal rate on the PCA, or given the clinical situation, as a long-acting formulation equivalent to the amount of demand doses received. In opioid tolerant patients, a dose equivalent to 10% to 20% of the patient's total 24-hour oral requirement should be administered as an intravenous bolus (see box on Relative Potencies of Commonly Used Opioids) and titrated, as above, every 15 minutes until pain is controlled and acceptable to the patient. For example, a patient receiving oxycodone sustained release 60 mg twice daily, should be prescribed morphine 5 to 10 mg intravenously every 15 minutes as needed (oxycodone 120 mg is approximately equivalent to 180 mg of oral morphine, or 60 mg of intravenous morphine; take 10% to 20% of this dose). The long-acting opioid should be continued or converted to a continuous infusion, or given as a basal rate via a PCA.

Once the patient has an acceptable level of analgesia, this dose can be converted to a sustained release formulation, or to another equivalent long-acting opioid. If morphine is used, for example, the patient will need three times the parenteral dose that was effective. For example, a patient who requires 10 mg of morphine per hour (i.e., 240 mg/24 hours given intravenously) will need 720 mg/day of the oral sustained-release agent (240 mg every 8 hours). This can also be given orally as 360 mg every 12 hours. Short-acting immediate-release morphine should be available for rescue dosing at 10% of the total daily dose. For this patient, 60 to 90 mg every 3 to 4 hours is recommended. If the amount of opioid taken as a rescue dose is significant (>25% of the daily dose) for 1 or 2 days, the total dose of long-acting agent is adjusted upward accordingly.

In the outpatient setting, patients with chronic, moderate-to-severe pain can be treated with oral pain medications, e.g., morphine 5 to 15 mg (or an equianalgesic dose, e.g., oxycodone 5 to 10 mg), and titrated in a similar fashion. The peak effect of most oral opioids is approximately 60 minutes, so the patient should be reassessed 60 minutes following the dose for analgesic efficacy and side effects. The same strategy as above can be used for opioid-tolerant patients, i.e., 10% to 20% of the basal dose can be given for additional analgesia and titrated to effect.

Agents to prevent side effects should be started once opioids are initiated. All patients should be prescribed a stimulant laxative, for example, senna (one or two tablets orally daily to twice daily, up to a maximum of eight pills per day), plus or minus a stool softener, for example, Colace 100 mg three times per day. If a more potent laxative effect is needed, lactulose (15 to 30 mL) or polyethylene glycol (17 g) is added. In opioid-naïve patients, prochlorperazine (Compazine 10 mg taken orally two or three times daily) is prescribed as needed to treat nausea. Other antiemetics may be prescribed instead, depending on the desired side effect profile; 5HT3 blocking medications, for example, are constipating and can cause QTc prolongation and headaches, but are not sedating like prochlorperazine.

Opioid Analgesics

Patient Education and Risk Assessment

To ensure patient adherence with an opioid prescription, education of members of the health care team, the patient, and the family is often required to dispel the many misconceptions associated with opioid therapy.[5]

Fear of addiction is a common cause of inadequate prescribing of opioids and a barrier to their acceptance by patients.[5] Patient adherence can be improved by providing a full explanation of the differences between addiction and physical dependence, education regarding the appropriate use, storage, and disposal of opioid medications, and the risk factors for opioid misuse. Patients may also fear that if they take opioid medications for moderate pain, the medications will no longer be effective if more severe pain occurs. Because this fear, if unexpressed, can lead to undertreatment, the topic should be addressed even if the patient does not raise the question. A functional goal of therapy, such as returning to a favorite activity or reinstituting normal activities of everyday life, may enable the patient and the family to accept the opioid. Misconceptions about religious teachings may prevent health care personnel, patients, and their families from giving or accepting adequate pain medication. Roman Catholics, for example, may not be aware of the church's position, as stated in the current Catechism, that opioids may be used at the approach of death even if their use to manage pain may unintentionally shorten the patient's life. The Church does not consider this use of pain medication to be a means of suicide or euthanasia.[5] Regardless, it is important to perform a risk assessment each time an opioid is being considered, to inform decision-making about risk of abuse. There are several validated tools available to facilitate this, such as the Opioid Risk Tool (ORT). Many states now also mandate checking a state-wide prescription monitoring system before prescribing an opioid, to ensure that a patient is not obtaining multiple prescriptions from various clinicians. As part of a high-quality opioid risk assessment, one must also consider the additive risk of the patient's entire medication list, as the combination of an opioid plus other medication classes can increase the risk of a serious or fatal adverse event (e.g., an opioid plus a benzodiazepine).

Choice of Medication

Because a wide variety of medications are available, pharmacokinetic considerations and side-effect profiles should be weighed when choosing opioid agents. Intermittent moderate-to-severe pain lasting hours to several days is amenable to oral analgesics with short half-lives (3 to 4 hours) with appropriate potency (e.g., immediate-release oxycodone, morphine, hydromorphone [Dilaudid], or oxymorphone [Opana] when available). Severe pain of relatively constant intensity should be treated with oral sustained-release morphine or oxycodone taken every 8 or 12 hours,[1,2] hydromorphone (Exalgo) taken every 24 hours, oxymorphone (Opana ER) taken every 12 hours, hydrocodone (Zohydro ER, Hysingla ER) taken every 12 hours, methadone taken every 6 to 8 hours, or transdermal fentanyl renewed every 48 to 72 hours. Twelve- to 24-hour formulations of oral morphine (e.g., Kadian, Avinza) are also available; for patients unable to take pills, the capsule can be opened and the pellets sprinkled on food or suspended in water and given through a feeding tube (see box on Relative Potencies of Commonly Used Opioids).[5]

Practical Considerations When Using Opioids

Drugs with short half-lives should be used for "rescue doses" given for incident pain (i.e., pain with movement) and for between-dose pain exacerbations often referred to as "breakthrough pain." The dose of the rescue medication is usually calculated as 10% to 20% of the total 24-hour dose, although there is no evidence for this heuristic.[23,24] For example, if a patient is receiving 300 mg of oral sustained-release morphine twice each day, the rescue dose is 10% to 20% of 600 mg, which is 60 to 120 mg of short-acting morphine. Agents with short half-lives should also be used in older patients and in patients with impaired renal or hepatic function.[5] For patients with a history of drug abuse, agents with longer half-lives, such as methadone, are preferred.

There is considerable variability with respect to the side effect profile of the various opioids in each patient. Therefore it is often useful to switch to another agent if a patient is experiencing dose-limiting side effects with the initial opioid chosen, or inadequate analgesia despite escalating doses amid prior efficacy of this agent. This practice is often called "opioid rotation." For example, if the patient on morphine experiences persistent or debilitating nausea, the rotation to another opioid at an equianalgesic dose should be considered (see box on Relative Potencies of Commonly Used Opioids). Because of incomplete crosstolerance, the initial dose for patients taking higher doses of opioids should be reduced by approximately 25% to 50%. The short-acting rescue medication can provide relief if this initial dose does not prove adequate.

Methadone is increasingly used for patients with moderate-to-severe pain. It is by far the least expensive of the opioids; can be given

RELATIVE POTENCIES OF COMMONLY USED OPIOIDS

Drug	Epidural	SC or IV (mg)	PO (mg)
Morphine	1	10	30
Codeine		130	200
Oxycodone		N/A	20
Hydromorphone	0.15	1.5	7.5
Methadone[a]		[a]	
Oxymorphone		1	10
Levorphanol		2	4
Fentanyl		0.1	N/A
Meperidine (Demerol)[b]		75	300

[a] Methadone is approximately half as potent orally as it is intravenously. It is usually not given SC because of local irritation. Standard equianalgesic tables do not reflect methadone's potency when used in repeated doses.

[b] Not recommended for patients with chronic pain.

IV, Intravenous; *N/A*, not applicable; *PO*, oral; *SC*, subcutaneous.

by the oral, sublingual, rectal, intravenous, and epidural routes; and may have particular usefulness in patients with poor tolerance to other opioids. Methadone has anecdotally been used for neuropathic pain; however, recent clinical trials have not demonstrated this benefit.[25] Methadone is structurally unrelated to morphine and fentanyl and can be used in the rare case of true allergy to these medications. It is also helpful when patients have neurotoxic side effects of other opioids. Methadone is a potent μ-opioid receptor agonist. The l-isomer has higher binding affinity for delta opioid receptors, which reduces tolerance, while the d-isomer has *N*-methyl-D-aspartate (NMDA) receptor antagonism and 5-hydroxytryptamine and norepinephrine reuptake blockade, which may be helpful in providing analgesia.[25] Patients with neuropathic pain and patients taking opioids chronically have increased levels of NMDA receptors in the dorsal horn of the spinal cord. NMDA antagonizes the activity of the opiate receptors. Blocking the NMDA receptors therefore enhances the analgesic effect of externally administered opioids. Ketamine, a pure NMDA antagonist, similarly enhances opioid efficacy but is associated with more cognitive side effects than methadone.

Methadone interacts with inducers and inhibitors of the cytochrome P450 system. It is extensively metabolized by CYP1A2, CYP3A4, and CYP2D6; the first two are induced by several drugs and other substances (e.g., cigarette smoke), and the last enzyme has a genetic polymorphism. Drug levels of desipramine and zidovudine increase when patients are receiving methadone. Drugs that lower the levels of methadone include phenytoin (by 50%), phenobarbital, carbamazepine, rifampicin, and risperidone, each of which has precipitated withdrawal symptoms.[26] Drugs that raise the serum methadone levels include ketoconazole, fluconazole, fluoxetine, and fluvoxamine. The selective serotonin reuptake inhibitors (SSRIs) (except venlafaxine) may raise methadone levels in CYP2D6 rapid metabolizers. Owing to these complexities, it is recommended to consult with an anesthesia pain specialist, palliative care specialist, and/or pharmacist when prescribing methadone.

Methadone can cause prolongation of the QT interval. A mean methadone dose of 400 mg/day (standard deviation: 283 mg) was found in 17 patients with torsades de pointes. In an evaluation of reports of methadone-related adverse events to the US Food and Drug Administration (FDA), approximately 1% of the greater than 5000 reports were of QT prolongation or torsades de pointes. The median dose was 345 mg with a range of 29 to 1680 mg. Drugs that also prolong the QT interval, such as metoclopramide and olanzapine, should be used with caution in patients receiving significant doses of methadone. Gabapentin, the drug used most often as a neuropathic pain adjuvant, does not interact with methadone metabolism. There is insufficient evidence to recommend a screening interval or dose threshold for detecting methadone-induced QTc prolongation, so overall caution and attention are warranted.[27]

Other difficulties with using methadone lie in its variable and long biologic half-life, and the controversy about its equianalgesic dosing range. Some studies have reported that the equianalgesic dose of morphine to methadone varies as the dose of morphine increases.[5] Dose ratios vary from 4:1 at morphine doses of 30 to 90 mg, to 6:1 at 90 to 300 mg, and to 8:1 at doses of more than 300 mg of morphine. Other studies report a ratio of 20:1 for doses of oral morphine equivalents greater than 1000 mg. Some physicians advise a 3-day conversion to methadone. On the first day, the dose of the old opioid is reduced by one-third, and one-third of the calculated dose of methadone is given; the second day, the dose of the remaining opioid is reduced by half, and the dose of methadone is only increased if the patient is experiencing moderate-to-severe pain; the third day, the old opioid is discontinued, and the standing dose of methadone is adjusted to reflect the rescue doses.[28] When converting patients directly from intravenous fentanyl to intravenous methadone, a conversion ratio of 25 μg/h of fentanyl to 0.1 mg/h of methadone has been found in a pilot study to be a safe and effective initial infusion rate.[28]

A relatively new opioid to the US market that is now available in both extended release and immediate release is oxymorphone. Oxymorphone extended release has been found to provide safe and effective pain relief for cancer pain.[29] Oxymorphone extended release is dosed twice daily and is about twice as potent as oxycodone.[30]

Levorphanol, which is chemically similar to dextromethorphan (an NMDA antagonist and cough suppressant), is a potent opioid that may be considered for patients with severe cancer pain. It was originally synthesized as an alternative to morphine more than 40 years ago. It has a greater potency than morphine, approximately five times as potent in its oral formulation. Analgesia is achieved through its agonistic activity at μ-, δ-, and κ-opioid receptors, as well as by its antagonism of NMDA receptors. Levorphanol can be given orally, intravenously, and subcutaneously.

Buprenorphine has long been used to treat patients with addiction as an alternative to methadone. It is available buccal/sublingually, intravenously, and now as a transdermal patch. Buprenorphine has been shown to be very effective in treating cancer pain (including neuropathic) and provides several important advantages over other opioids: it is associated with less cardiotoxicity (does not significantly prolong the QTc interval), respiratory depression, cognitive impairment, and constipation, and is one of the safer opioids to use in older patients or patients with renal dysfunction.[31]

Meperidine is 8 to 10 times less potent than morphine and has a short duration of action, approximately 2 to 3 hours. Normeperidine, an active metabolite which induces dysphoria, is excitatory to the CNS and can cause agitation, tremors, myoclonus, and seizures, especially in high doses, with prolonged use or in renal failure.[5] Normeperidine has a half-life of 13 to 24 hours, which can lengthen with renal failure. The seizure incidence is further increased if the opioid antagonist naloxone (Narcan) must be given. Therefore meperidine is not recommended for use in patients with long-lasting moderate-to-severe pain.[1,2]

Routes of Delivery

Opioids can be delivered noninvasively (orally, rectally, transmucosally, or transdermally) or invasively (subcutaneously, intravenously, or by spinal infusion). For patients switched from one route to another such as oral or rectal to parenteral or spinal medication, or vice versa, the dose must be converted accordingly to avoid overdose or undertreatment (see box on Relative Potencies of Commonly Used Opioids).

Oral Route

Most patients can achieve excellent pain relief with short-acting and/or sustained-release oral opioid preparations. Close attention, frequent follow-up, and ongoing adjustment and titration are often needed to achieve this, however. The typical onset of short-acting opioids via the oral route is 45 minutes to 1 hour, with a typical duration of action around 3 to 4 hours. When tablets and capsules are not feasible, many liquid forms are available in various concentrations. Some solutions do contain alcohol, which can be irritating to patients with oral lesions.

Rectal Route

Rectal opioids (i.e., morphine, oxymorphone, and hydromorphone) replace subcutaneous injections in patients who are suddenly unable to take oral medications. They have approximately the same potency and half-life as orally administered agents[5] and must therefore be administered frequently. Oxycodone has been shown to have a similar mean bioavailability but with a large interpatient variability but longer duration of activity (8 hours). Although not approved by the FDA, in single-dose bioavailability studies of sustained-release morphine preparations, despite delayed absorption from the rectal route, total morphine absorption over 24 hours was equivalent, whether the drug was given orally or rectally.[5]

Transdermal Route

The transdermal fentanyl patch delivers the lipophilic fentanyl into the fat-containing areas of the skin. The drug diffuses continuously from the patch's reservoir through a rate-controlling membrane and is absorbed from the skin depot into the bloodstream, where it is rapidly metabolized.[5] The onset of pain relief is delayed about 12 hours, and a relatively constant plasma concentration of fentanyl is not reached until about 14 to 20 hours after the initial patch is placed.[5] Liberal rescue medication must therefore be provided during the first 24 hours of use of the patch. Similarly if a patient develops signs of fentanyl overdose, naloxone (Narcan) must be given until the skin reservoir has become depleted. About 50% of the drug is still present 24 hours after patch removal. Converting patients from oral or parenteral medication to the patch is easily accomplished[5] (see box on Conversions Between the Transdermal Fentanyl Patch and Morphine). A new patch is applied every 72 hours, although up to 25% of patients require a new patch every 48 hours, thus it is important to ask patients specifically about their pain relief in the last 24 hours of that 72-hour interval.

The transdermal system is an effective method of delivering pain relief for patients with a stable level of chronic moderate-to-severe pain, no oral route available, or no desire to take pills. Side effects include those caused by the contact adhesive along with those commonly associated with other opioids, but they may be better tolerated than those caused by morphine.

CONVERSIONS BETWEEN THE TRANSDERMAL FENTANYL PATCH AND MORPHINE

	Morphine (mg/24 h)	
Fentanyl (μg/h)	Oral	IM or IV
25	50	17
50	100	33
75	150	50
100	200	67
125	250	83
150	300	100

IM, Intramuscular; *IV*, intravenous.
Data from Miaskowski C, Cleary J, Burney R, et al. *Guideline for the Management of Cancer Pain in Adults and Children, Aps Clinical Practice Guidelines Series, No.3.* Glenview, IL: American Pain Society; 2005.

The transdermal system should not be used in patients with sepsis, those experiencing acute pain, those with markedly fluctuating opioid requirements, cachectic patients, or individuals with significant dermatologic insults (i.e., skin graft-versus-host disease [GVHD] or diffuse varicella). When the patient's temperature rises to 40°C, drug absorption from the skin can increase by as much as 35%. If hepatic function is impaired or sepsis or shock develops and blood flow to the liver decreases, plasma concentrations may rise sharply. Patients with cachexia lack the subcutaneous tissue necessary for formation of a drug reservoir. Lower doses may also be required in older patients and in those with respiratory insufficiency.

Transdermal buprenorphine (Butrans) patches have been shown to be safe and effective in patients with cancer pain.[32] They can be used alone or in combination with other opioids without reported problems, and unlike other opioids, which can cause a hyperalgesia effect from long-term use, buprenorphine has been described to exert an antihyperalgesic effect. A lack of immunosuppression and safety in renal insufficiency make buprenorphine ideal for the treatment of cancer patients. Due to the risk of QTc prolongation the transdermal patch carries an FDA warning against exceeding 20 μg/h.

Transmucosal Route

Transmucosally administered fentanyl induces rapid analgesia with a short duration of effect (≈1 hour) and is an effective treatment in the management of breakthrough pain.[24] Oral transmucosal fentanyl citrate (Actiq), fentanyl buccal tablet (Fentora), fentanyl buccal soluble film (Onsolis), fentanyl sublingual tablets (Abstral), and fentanyl sublingual liquid spray (Subsys), as well as a fentanyl nasal spray (Lazanda) are the available transmucosal fentanyl products. They have been found to be both efficacious and safe in the treatment of cancer-related breakthrough pain.

Subcutaneous and Intravenous Routes

Subcutaneous or intravenous administration of opioids can provide pain relief in the shortest amount of time with minimal oversedation. The drugs can be delivered by portable infusion pump that is initiated or continued in the home.[4] Guidelines for their use are available. PCA systems for subcutaneous or intravenous drug delivery have the advantage of responding to the individual patient's threshold for pain while eliminating delays when nurses must administer supplemental medication. The pumps can administer a continuous fixed infusion of the opioid chosen and allow the patient to self-administer boluses of additional medication at frequencies chosen by the ordering clinician. By recording the additional amounts of self-administered medication, the devices also facilitate the adjustment of the continuous dose required for pain relief.

Spinal Route

Epidural or intrathecal opioid infusions can be helpful for select patients. The infused opioids block pain transmission by binding to receptors in the dorsal horn of the spinal cord. Because the drug is being infused in close proximity to the spinal cord, only a small amount of opioid is needed, and the systemic side effects are reduced. Problems with this delivery system in patients who are not opioid naive include pruritus, respiratory depression, and sedation. If tolerance to the opioid develops and higher doses are required for relief, the incidence of side effects may approach that of systemically administered opioids.[33,34] Addition of local anesthetic or α-adrenergic agent (e.g., clonidine) or other agents[14] to the epidural opioid infusion allows for fairly rapid lowering of the opioid concentration and reestablishing opioid sensitivity but can cause hypotension.[35]

Management of Opioid-Related Side Effects

Sedation

The addition of 2.5 to 7.5 mg of dextroamphetamine or methylphenidate[5] (taken orally twice daily) has been shown to reduce opioid-induced sedation and at times allow for escalation of opioid doses without sedation. These medications also improve cognitive function and symptoms of depression. Methylphenidate may also enhance the analgesic effects of opioids.[5] They should be avoided in patients with anxiety, moderate-to-severe hypertension, agitation, thyrotoxicosis, tachyarrhythmias, severe angina pectoris, and closed-angle glaucoma. Modafinil (Provigil), a novel psychostimulant with a mechanism of action different than the amphetamine derivatives, which is approved for narcolepsy and fatigue related to multiple sclerosis, has also been found to be effective for opioid-related sedation.[5]

Constipation

Constipation is the most common opioid-induced side effect.[2] Laxatives should therefore be given routinely, not on an as-needed (PRN) basis,[1,2,5] to patients treated with any of the drugs listed in the box on Relative Potencies of Commonly Used Opioids. Detailed bowel preparation recommendations can be found, but no regimen has been studied in a controlled fashion. Commonly used stool softeners and stimulants include docusate sodium, senna, lactulose, and polyethylene glycol. A combination of a stool softener and laxative seems to be a rational choice for patients taking chronic opioids (e.g., docusate sodium with senna). Promotility agents most directly counter the mechanism of opioid-induced constipation. Bulk-forming laxatives such as psyllium and methylcellulose should be avoided because they increase stool volume without promoting peristaltic action. For refractory opioid-induced constipation, a trial of oral naloxone, methylnaltrexone, or alvimopan may be initiated.[5] These μ-opioid receptor antagonists (RAs) act locally to reverse the effects of opioids on the gut. There is minimal systemic absorption with oral naloxone and subsequently a low risk of precipitating opioid withdrawal or worsening pain at low-to-moderate doses (1.6 to 12 mg/day). Methylnaltrexone (administered subcutaneously)[5] and alvimopan (oral) do not cross the blood–brain barrier and therefore do not cause opioid withdrawal or worsening pain. There is now an oral formulation of methylnaltrexone available as well.

Nausea

Prochlorperazine (10 mg taken two or three times daily) or metoclopramide (10 mg taken three to four times daily) can prevent the nausea that occurs in most patients during the first days of opioid therapy. Relieving constipation or changing the opioid (e.g., from morphine to oxycodone) often eliminates the later development of nausea. Rarely, patients need oral or intravenous ondansetron (8 mg taken two or three times daily). Attention may be needed to QTc prolongation with all of these medications, especially if there is concomitant prescribing of multiple QT-prolonging agents.

Respiratory Depression

Naloxone (Narcan), given intravenously, reverses opioid-induced respiratory depression, although repeated doses are often required.[5] Respiratory depression can occur in patients with mild-to-moderate pain during the initial use of opioids, although it is rare in patients with severe pain and in those chronically receiving opioids. Caution should be exercised before administering naloxone to patients who are chronically receiving opioids to avoid precipitation of severe pain and withdrawal. In such cases, it is inadvisable to administer the usual 0.4 mg/mL dose. Rather, 0.4 mg of naloxone should be diluted with 9 mL of saline and 1 to 2 mL (0.04 to 0.08 mg) of this dilute mixture given every 2 to 3 minutes until the patient is rousable and breathing at least 10 times/min. Do not give enough to fully waken the patient or withdrawal is likely to ensue.[1] In a comatose patient, endotracheal tube placement is recommended to prevent aspiration from the salivation and bronchial spasm that will be induced.[1] Naloxone should not be administered to an alert patient. Concomitant prescribing of multiple sedating medications may increase the risk of respiratory depression and related complications, so attention is needed to the patient's entire medication list; common medications of concern include benzodiazepines and sedative/hypnotic agents.

Adjuvant Analgesics

Adjuvant analgesics are a diverse class of medications, which typically have indications for conditions other than pain. They have analgesic properties and are often used when an opioid regimen alone is unable to provide sufficient analgesia or is associated with dose-limiting side effects.

Neuropathic Pain

Adjuvant agents for patients with neuropathic pain include anticonvulsants, antidepressants, α_2-adrenergic agonists, corticosteroids, topical agents, γ-aminobutyric acid (GABA) agonists, and NMDA RAs.[1,2,5,36] However, the analgesic antidepressants and anticonvulsants are typically preferred for treating neuropathic pain secondary to cancer.[37]

The anticonvulsants gabapentin (Neurontin) and pregabalin (Lyrica) have the fewest side effects and are very effective for patients with neuropathic pain from tumor, peripheral neuropathy from tumor or treatment, and PHN.[36] Despite their names, they have no effect on GABA receptors, but rather bind to the α-2-delta subunit of the N-type calcium channels in neurons within the dorsal horn, thus inhibiting calcium influx and diminishing neuronal hyperactivity. To minimize sedation, doses should be low at first (e.g., gabapentin 100 mg three times daily or 300 mg at bedtime; pregabalin 50 mg twice a day) and should be increased as tolerated every 3 to 5 days until analgesia is achieved. The effective dose of gabapentin varies between 900 and 3600 mg/day in divided doses and that of pregabalin is 150 to 300 mg twice a day. The pharmacokinetics of gabapentin are unique in that it has a ceiling effect related to a saturable transport mechanism in the gut, such that the effects of this drug may plateau during dose escalation.[37] The most common dose-limiting side effect is sedation. Gabapentin and pregabalin need to be renally dosed in patients with decreased creatinine clearance. Peripheral edema related to gabapentin or pregabalin may require diuretics. Pregabalin's gastrointestinal absorption is proportional to the dose throughout the effective dose range, making titration simpler. Other, generally less effective anticonvulsants used for neuropathic adjuvants include phenytoin, carbamazepine, lamotrigine, topiramate, and tiagabine.

The tricyclic antidepressants (TCAs; e.g., amitriptyline, nortriptyline) are effective agents for neuropathic pain.[5] The TCAs, when used as adjuvant analgesics, are effective faster and at lower doses than when they are used as antidepressants (e.g., amitriptyline is effective within 2 to 3 days at 50 to 100 mg/day). However, because of their anticholinergic side effects they should be started at doses of 10 to 25 mg at bedtime and used with caution in older patients and in patients who have cardiac conduction abnormalities or bladder outlet obstruction. Combination therapy with gabapentin and nortriptyline has been shown to be more effective than either drug alone in patients with diabetic neuropathy and PHN.[38]

Selective serotonin and norepinephrine reuptake inhibitors (SSNRIs; e.g., venlafaxine and duloxetine) have been shown to be analgesic for a number of neuropathic pain syndromes. There is less evidence supporting the use of SSRIs for neuropathic pain.

Corticosteroids given epidurally, intravenously, or orally are useful as antineoplastics (e.g., in leukemia, lymphoma, and myeloma) and can also provide nonspecific relief for patients with spinal cord compression and plexus infiltrations. Doses of 16 to 100 mg of dexamethasone are needed to reduce vasogenic edema in spinal cord compression,[5] but lesser doses (6 to 20 mg/day) can be helpful in patients with plexus injuries. Patients must be monitored for the development of oral or esophageal candidiasis and steroid-induced delirium.

Bone Pain

Adjuvants for bone pain include NSAIDs, corticosteroids, bisphosphonates, receptor activator of nuclear factor κ-B ligand inhibitors (e.g., denosumab), and the radiopharmaceuticals strontium chloride (^{89}Sr) and samarium153-lexidronan.[5] Multiple studies have demonstrated the efficacy of bisphosphonates in reducing skeletal complications and pain from bone metastases.[5] Pamidronate and zoledronate are recommended for patients with multiple myeloma and other hematologic malignancies with painful bone lesions. Calcium and sometimes vitamin D supplementation (especially for denosumab) are often needed.[39] Also, the long-term use of bisphosphonates is associated with a small but meaningful risk of osteonecrosis of the jaw.[39] The limitations of radiopharmaceuticals include cost, logistical issues related to administration, and cytopenias.[5] Given the limited evidence available, a recent Cochrane review did not support the use of calcitonin for control of pain from bone metastases.

Cannabinoids

Long used empirically for their analgesic and antiemetic properties in a wide range of illnesses, cannabis and cannabinoid therapies have been subjected to an increasingly large number of controlled clinical trials (of varying size and quality) over the last several decades.[40] Oral cannabis, used for breakthrough pain, was studied in a recent multicenter randomized controlled trial, involving 360 patients, who were started on a long-acting opioid. The study showed analgesic efficacy in the low and medium dose ranges, which were also well tolerated.[41] Inhaled cannabis, used for nausea and vomiting secondary to active cancer chemotherapy, was studied in three randomized controlled trials, involving 43 subjects in total, which demonstrated inhaled cannabis to be an efficacious antiemetic. Additional studies have provided evidence for its effect on spasticity, appetite stimulation, and insomnia. Cannabis is not available medically in some states. There is also potential risk of fungal pneumonias in patients with hematologic malignancies who smoke cannabis, so patients should be advised about this possibility, and consider alternate administration routes in areas where cannabis is legally available for medical use.

SPECIFIC CLINICAL PROBLEMS

Oral Complications

Oral complications of chemotherapeutic and bone marrow transplant regimens can be frequent causes of pain. A thorough dental evaluation and prompt treatment of infections can minimize the discomfort arising from underlying periodontal disease and caries; secondary bacterial, viral, and fungal infections; and mucositis.[42] Preventive regimens include saline, sodium bicarbonate, chlorhexidine gluconate rinses, acyclovir, antifungals, and ice. Palifermin (recombinant human keratinocyte growth factor [KGF-1]) is used for the prevention and treatment of mucositis induced by conditioning regimens for hematopoietic stem cell transplants (SCTs).[5] Amifostine is a thiol compound that is a selective cytoprotective agent approved for salivary gland protection in patients receiving radiation therapy.[43] The benefit of using colony-stimulating factors in the treatment of oral mucositis has been confirmed in at least four controlled trials.[44] They have not achieved widespread use, possibly because of their high cost.

Anesthetic cocktails composed of agents such as viscous lidocaine (Xylocaine), dyclonine hydrochloride, or a slurry of sucralfate provide temporary relief from oral mucositis-related oral pain. A variety of mucosal-coating agents have been used to protect mucosal surfaces of the oral cavity including Orabase, Episil, oral antacids, and Gelclair. There is little evidence from randomized trials to support any benefit from these preparations. Gelclair, a bioadherent gel that adheres to the oral surface, creating a protective barrier for irritated tissue, showed a reduction in oral discomfort within 5 to 7 hours of initial treatment in an uncontrolled, open-label study of 30 hospice patients (only three of whom had chemotherapy-related mucositis).[45] The more severe cases, occurring in bone marrow transplant recipients, usually require infusional opioid therapy delivered by standard drip or PCA. Pilocarpine (5 to 10 mg three times daily 1 hour before meals) may improve xerostomia from neck irradiation. However, caution is warranted because of reported side effects of glaucoma and cardiac problems. Sugar-free hard candy is also useful for opioid-induced xerostomia and dysgeusia. Doxepin oral rinse has been shown in several studies to be effective in reducing oral mucositis pain in patients receiving radiation for head and neck cancer, or with mucositis due to stem cell transplantation.[46]

Postherpetic Neuralgia

PHN, defined as pain persisting beyond 4 months from the initial onset of the rash, can be a difficult problem for patients with hematologic disorders and has been the subject of several reviews. The anticonvulsant medications gabapentin, pregabalin, and valproic acid are especially useful in reducing the lancinating component of the various pain syndromes generated by this infection. A 2011 systemic review identified four placebo-controlled randomized trials, with two trials evaluating immediate-release gabapentin at doses between 1800 and 3600 mg daily showing benefit compared with placebo for the outcome of "much or very much improved" (38% vs. 20%).[47] Pregabalin in randomized studies with patients with PHN has shown improvement in sleep and decrease in pain at doses of 150 to 600 mg daily.[48] Because of the risks associated with physical dependence, tolerance, addiction, and overdose, many experts consider opioids as second- or third-line options for PHN.[49]

TCAs are effective for PHN.[50] One trial concluded that nortriptyline was better tolerated than amitriptyline.[51] Older patients, however, often do not tolerate the anticholinergic side effects, principally sedation and dry mouth, and therefore nortriptyline (Pamelor), a less anticholinergic TCA, may be useful in these patients. Topical lidocaine (5%) has been used for the relief of pain associated with PHN; however, its role has not been established.[52] There are limited data on the efficacy of topical capsaicin (0.075%).[53] Available evidence of botulinum toxin injection for PNH has not been well studied, but available evidence suggests it is effective and well tolerated.[54] Patients with severe pain refractory to these therapies may benefit from a combination of intrathecal methylprednisolone and lidocaine.[55]

Sickle Cell Anemia

Patients with sickle cell anemia have chronic and episodic pain despite optimal medical therapy, and 60% of patients with sickle cell anemia will have an episode of severe pain each year. Chronic arthritic pain can be treated with physical therapy and full doses of antiarthritic medication, but some patients require low doses of chronic opioid therapy to maintain independent functioning. Several studies have confirmed the safety and efficacy of long-term opioids in the treatment of pain of nonmalignant origin. In some cases, joint replacement may be required. The best approach to managing acute pain in sickle cell anemia is to reduce or prevent painful vasoocclusive crises to begin with, as is discussed in the relevant chapter on this topic. Here we discuss only symptomatic management of pain once it occurs.

When a patient with sickle cell anemia experiences pain, it is important to attempt to define the precise cause of the pain before attributing it to a vasoocclusive crisis. Acute vasoocclusive pain may occur along with the chronic pain caused by the long-term complications of compression fractures, avascular necrosis, arthropathies, fractures, avascular necroses, and leg ulcers.[56]

Treating patients with sickle cell pain is complex and requires understanding that much of the pain in adults with this illness is chronic with intermittent, recurring painful episodes. For mild pain, nonopioid therapy such as NSAIDs or acetaminophen with oxycodone or hydrocodone should be considered. However, because of possible compromise of renal blood flow in these patients and the risk of acute renal failure, NSAIDs should probably not be used beyond 5 days.[2] Uncontrolled severe pain accounts for more than 90% of hospital admissions in adults with sickle cell disease. Using short-acting analgesics on an “as-needed” basis exposes the patient to periods of insufficient analgesia, anticipation, and anxiety. Their repeated requests for medication to relieve their ongoing pain may be mistakenly interpreted as “drug-seeking behavior,” and they may be unfairly stigmatized. Thus, intravenous analgesics should be started as a continuous infusion or with PCA. When adequate analgesia is obtained, a long-acting opioid or a sustained-release opioid may be initiated with intermittent use of rescue medication. In adult patients with frequent episodes of painful crisis, the use of long-acting opioid medications reduced visits to the emergency department and hospitalizations, and shortened the lengths of stay in hospital. Meperidine should be avoided in this population and has been associated with seizures in 1% to 12% of these patients.

Patients With Opioid Addiction

In order to identify and treat patients with opioid addiction, the Food and Drug Administration Amendments Act (FDAAA) of 2007 established the requirement for postmarketing studies and mandated the implementation of Risk Evaluation and Mitigation Strategies (REMS).[57] Statewide Prescription Drug Monitoring Programs (PDMP) were established to track patients with prescriptions for controlled substances from multiple practitioners (e.g., I-STOP in New York State). These systems allow the practitioner to easily reference which scripts a patient has filled from which practitioner. Many guidelines for treating non-malignant chronic pain with opioids exist. Patients with cancer are not immune to the risks of opioid misuse and some patients may have a history of substance abuse. It is important to screen all patients for a history of or ongoing substance misuse, including with a formal opioid risk assessment tool, several of which are available. Patients with risk factors should be managed more strictly with the use of medication management agreements, urine toxicology screening, pill counts, and possibly more frequent visits, with prescriptions for shorter durations.

Hematopoietic Stem Cell Transplantation

While some studies have reported pain after hematopoietic stem cell transplantation, thought to be secondary to bone marrow expansion during the engraftment phase,[58] other studies have incidentally reported improvement in pain in patients with sickle cell disease after completion of successful transplantation. While there are no studies that specifically look at pain outcomes, several studies report positive results. One study, which involved 50 children (26 with long-term follow-up) with SCTs, reported that 22 of the children experienced no further episodes of pain after transplantation. It is notable that the age range was 4 to 14 years of age, which is likely to be too young to start developing the serious long-term effects of sickle cell disease.[59] Subsequent studies have demonstrated similar results in children who undergo SCT.[60] A recent study of adult patients with sickle cell disease who underwent SCT demonstrated that while these patients do continue to take opioids, they require lower doses. Pain in these patients is thought to be secondary to sickle cell disease injury prior to SCT.[61]

Graft-Versus-Host Disease

For patients who have undergone stem cell transplantation, GVHD can be a significant problem. The usual triad of GVHD includes hepatitis, dermatitis, and gastroenteritis. Patients are often unable to take oral, rectal, subcutaneous, or transdermal opioids because of the effects on the skin (GVHD), lining of the gastrointestinal tract (mucositis, infection, and GVHD), and thrombocytopenia. Polyarthritis and musculoskeletal manifestations can cause significant pain (Table 99.3). Therefore pain management with intravenous opioids is often a necessity. The intestinal involvement that usually causes the most physical pain includes abdominal cramping and voluminous diarrhea. Treatment often begins with intravenous opioids given through a PCA pump. Addition of octreotide continuous infusion at 50 to 100 μg/h intravenously or intermittent dosing at 500 μg subcutaneously every 8 hours may be effective in decreasing the volume of diarrhea and level of abdominal pain.[5]

Peripheral Neuropathy Caused by Chemotherapy Agents

Several chemotherapy agents used in the treatment of hematologic malignancies can cause painful sensory peripheral neuropathy. The vinca alkaloids, most notably vincristine, are neurotoxic, but they are not always associated with painful neuropathy. Thalidomide, lenalidomide, pomalidomide, bortezomib, carfilzomib, cisplatin, oxaliplatin, and paclitaxel are all commonly used agents that carry a significant risk of causing painful peripheral neuropathy. The most common mechanism of neuropathy is damage to the axons starting with the most distal branches and is a result of chemotherapy’s ability to damage DNA replication, leading to apoptosis. The major manifestations are burning paresthesias of the hands and feet, and loss of reflexes. Paclitaxel also causes a motor neuropathy, which predominately affects proximal muscles.

Studies have evaluated numerous agents for prevention of painful peripheral neuropathy, although there have not been any magic bullets. Most of the research has focused on taxane and platinum-based chemotherapy agents. The American Society of Clinical Oncology (ASCO) has published a review of the available literature for prevention and treatment of chemotherapy-induced peripheral neuropathy (CIPN). Many vitamins and dietary supplements have been studied; however, most have not consistently shown benefit in larger randomized trials.[62] Specifically, the ASCO review indicates that acetyl-L-carnitine, vitamin E, all-*trans*

retinoic acid, glutathione, and calcium and magnesium infusions should not be utilized in the prevention of CIPN. Chemoprotectants have also not withstood scrutiny; amifostine, nimodipine, and others are not recommended. Although amitriptyline has not been shown to prevent CIPN, carbamazepine, oxcarbazepine, and venlafaxine have shown promise, although further evaluation is warranted.

Treatment of chemotherapy-induced painful peripheral neuropathy includes the usual agents used for patients with neuropathic pain from any etiology (i.e., anticonvulsants, TCAs, and occasionally tramadol or opioids). Duloxetine, an SNRI, has been shown to improve CIPN at a dose of 60 mg daily.[63] In addition to treating these painful symptoms of neuropathy, the doses of the chemotherapy often require reduction or even discontinuation of therapy.

Problems in Older Patients

Pain management in older patients is a highly prevalent problem. It is complicated by difficulties in pain assessment and by the altered pharmacokinetics of opioids and of psychotropic adjuvant medications. Older patients may underreport pain because of misconceptions that pain is part of the aging process or fears of addiction.[64] Physicians may ascribe observed limitations in social contacts and physical activities to age-related changes when they are pain-induced limitations.

Older patients are particularly susceptible to the side effects of NSAIDs and opioids, and patients taking them should be monitored closely.[65] In patients aged 70 to 89 years old, the volume of distribution for opioids is generally smaller, the drugs have longer plasma half-lives, and renal and hepatic clearances are decreased, all of which can prolong the duration of effect. The effective doses for these patients are half to one-fourth of those needed in younger patients. Drugs with short half-lives (e.g., morphine, oxycodone, hydromorphone) should be used, and initial doses should be low. Patients should be monitored carefully for the development of sedation or confusion, especially if they are receiving antihistaminic agents (e.g., famotidine, diphenhydramine), drugs with anticholinergic activity, or hypnotics.

Neuropathic pain syndromes are common in older adults, and the adjuvant analgesics gabapentin and pregabalin are often used. Common side effects include somnolence, dizziness, fatigue, and weight changes that can be problematic in the geriatric population.[66] Treatment should be initiated at 100 mg of gabapentin or 50 mg of pregabalin at bedtime, and close monitoring for side effects should occur before dose escalation. Acute urinary retention caused by opioids (especially in patients with prostatic hypertrophy) and the hypotension and tachycardia caused by tricyclic compounds can occur more frequently and be more clinically severe in this population. The starting dose of nortriptyline should be low (usually 10 mg at bedtime), and the dose should be slowly increased as tolerated. Treatment of opioid-related urinary retention may include generic Proscar (5 mg/day) in patients with benign prostatic hypertrophy and bethanechol (10 to 50 mg three times daily) to help increase bladder smooth muscle tone.

PATHOPHYSIOLOGY OF NAUSEA AND VOMITING

Nausea is the subjective sensation that precedes vomiting. It is caused by stimulation of one or more of four sites—the gastrointestinal tract, the vestibular system, the chemoreceptor trigger zone in the area postrema of the floor of the fourth ventricle, or higher centers in the CNS (Fig. 99.2). The gastrointestinal tract can activate the vomiting center by stimulation of mechanoreceptors or chemoreceptors on glossopharyngeal or vagal afferents (cranial nerves IX and X), or by release of serotonin from gut enterochromaffin cells, which in turn stimulates serotonin (5-HT3) receptors on vagal afferents. The vestibular system activates the vomiting center when stimulated by motion or disease (e.g., labyrinthitis) or when sensitized

by medication (e.g., opioids). Histamine (H1) and acetylcholine (M1) receptors are present on vestibular afferents. Endogenous or exogenous blood-borne toxins may activate chemoreceptors in the area postrema of the floor of the fourth ventricle via dopamine type 2 receptors. Finally, higher CNS centers may activate or inhibit the vomiting center. In addition, there may be direct activation of H1 receptors in the meninges secondary to increased intracranial pressure.

The means by which chemotherapy agents induce vomiting are still incompletely understood, but the most likely mechanism is believed to include stimulation of the chemoreceptor trigger zone.[5] Other causes of nausea and vomiting in hematologic patients include stimulation of the cerebral cortex, gastritis and gastroesophageal reflux disease, delayed gastric emptying, radiation enteritis, constipation, esophageal candidiasis, inner ear processes, hypoadrenalism, hypercalcemia, changes in taste and smell, and anticipatory nausea.[5]

Although the sites of emetic action of the chemotherapeutic agents have not been identified, blocking agents directed against type 3 serotonin receptors (5-HT3 receptors), dopamine (D2) receptors, and neurokinin (NK-1) receptors have been effective in inhibiting chemotherapy-induced nausea and vomiting (CINV).[5] Higher centers in the brain, such as the cortex, are also believed to be involved in producing anticipatory nausea and vomiting (ANV). Cognitive therapy, as well as antianxiety and amnesic agents, may provide effective antiemesis.

PATIENT ASSESSMENT

Risk factors for developing CINV include age younger than 60 years, female gender, history of motion sickness, and hyperemesis gravidarum.[5] Patients who have a history of alcohol intake of more than five alcoholic drinks per day (>100 g of alcohol) tend to have less nausea and vomiting. This has been studied carefully in patients receiving high-dose cisplatin therapy but has been anecdotally observed in patients receiving other agents.

Anticipatory Nausea and Vomiting

ANV is believed to be a classic conditioned response.[5] Chemotherapy administration (the unconditioned stimulus) results in nausea and vomiting (the unconditioned response). Clinic sights, smells, and sounds are the conditioned stimuli. After frequent pairings of chemotherapy administration and the clinic's sights, smells, and sounds, the responses (nausea and vomiting) can be triggered in the absence of any chemotherapy by the clinic's sights, smells, or sounds, or simply by seeing clinic personnel even at a location distant from the site of treatment.

Patients who are at risk for developing ANV are those who have already experienced posttreatment nausea and vomiting, therefore primary prevention of CINV is the best strategy. The risk of developing ANV increases with the increasing frequency, severity, and duration of the symptoms. Other possible predisposing factors include susceptibility to motion sickness, awareness of tastes or odors during infusions, younger age, lengthier infusions, greater autonomic sensitivity, and general anxiety or emotional distress.[5]

Acute and Delayed Chemotherapy-Induced Nausea and Vomiting

Acute CINV is defined as nausea, vomiting, or both occurring within 24 hours of administration of the agent. Although most drugs produce emesis 1 to 2 hours after they are given (in patients who have never received chemotherapy), the onset of emesis from high-dose intravenous cyclophosphamide is delayed until 9 to 18 hours after treatment, and nausea and vomiting from high total doses of cisplatin can occur 24 to 72 hours later (delayed CINV).

THERAPY

Antiemetic

Several effective antiemetics are used to prevent the nausea and vomiting induced in patients by treatment of their hematologic disorders with chemotherapy or radiation therapy. These antiemetic therapies markedly improve patients' quality of life. Most patients can expect complete control of vomiting,[67] and most patients also are free of nausea.

Most studies of the potent antiemetic agents have been conducted in patients receiving therapy with cisplatin, a drug of high emetic potential. Although cisplatin is not generally used to treat patients with hematologic malignancies, the data are included in the following discussion because the findings can be extrapolated to other drugs of equivalent or less emetogenic potential. When available, data regarding efficacy in patients receiving radiation therapy or emetogenic drugs commonly used to treat hematologic disorders are reviewed. The choice of antiemetic agents depends on the emetogenic potential of the chemotherapy or radiation therapy regimen, the side effect profiles of the antiemetic agents, and patient preferences and characteristics.

The emetogenic potentials of commonly used chemotherapeutic agents are outlined in the NCCN Clinical Practice Guidelines in Oncology Antiemesis Guideline (www.nccn.org). For patients being treated with chemotherapeutic agents with low or minimal emetogenic potential, no antiemetic therapy may be needed, or a single agent such as dexamethasone or metoclopramide may be sufficient. For drugs with higher emetogenic potential, standard antiemetic treatment usually includes combinations of several antiemetic agents along with agents designed to treat anxiety.

Combination Antiemetic

These combinations include a 5-HT3 RA such as ondansetron and a corticosteroid such as dexamethasone for moderately emetogenic regimens.[67] Recent NCCN guideline updates have re-classified some chemotherapy agents or regimens from moderately emetogenic to highly emetogenic, and also added recommendations for the use of NK-1 inhibitors in preventing CINV even for some moderately emetogenic regimens. Guideline updates now also include the option to use olanzapine as part of a triplet antiemetic strategy, since studies show it can be a helpful adjunct for reducing delayed CINV when used in combination with a 5-HT3 RA and a steroid (olanzapine is given 5 to 10 mg by mouth daily on days 1 to 3; the 10 mg dose can be quite sedating, and 5 mg may be just as effective). For highly emetogenic combination chemotherapy or regimens that include two moderately emetogenic agents, such as cyclophosphamide and Adriamycin, an NK-1 inhibitor such as aprepitant should be added to the antiemetic combination.[67] Optional lorazepam may be added for anxiety-related symptoms. It is important to give antiemetic therapy before administering chemotherapy agents and to continue for about 24 to 72 hours after the drugs have been given to prevent emesis. Patient-specific factors and preferences regarding degree of alertness can help the clinician choose an antiemetic regimen, as can the level of anxiety observed in the patient. For instance, younger patients have a higher incidence of CINV and of metoclopramide-related acute dystonic reactions; trismus or torticollis was seen in only 2% of patients older than 30 years of age but in 27% of younger patients. Therefore even if they are receiving only moderately emetogenic therapy, they may require an antiemetic regimen for high-emetogenic drugs.[67] Younger patients find cannabinoids (e.g., Marinol) more effective than do older patients because they can better tolerate the side effects associated with the therapeutic doses of these agents. Older patients also have high risks of extrapyramidal side effects and are more susceptible to anticholinergic and sedating side effects. 5-HT3 RAs are therefore preferred to regimens containing metoclopramide and diphenhydramine.

The antiemetic evidence behind the utilization of different medications changes over time. We recommend utilizing the ASCO clinical practice guidelines for recommendations on combination antiemetic regimens: http://www.instituteforquality.org/practice-guidelines.

Serotonin Receptor Antagonists: Ondansetron, Granisetron, and Palonosetron

Ondansetron, granisetron, and palonosetron are the best studied of the 5-HT3 RAs. This class also includes the drugs dolasetron and tropisetron. Several studies of patients receiving regimens that included cyclophosphamide, methotrexate, or doxorubicin showed significant efficacy and the superiority of ondansetron over placebo.

Ondansetron also demonstrates efficacy in patients with emesis (induced by non-cisplatin-containing chemotherapy) that has been refractory to standard antiemetics, with complete control achieved in 50% of these patients. When dexamethasone is added, the rate of control is as high as 91%. More recent evidence suggests, however, that although vomiting is rare with appropriate use of modern combination antiemetic regimens, breakthrough nausea is more common than previously realized. This has led to the shift from doublet to triplet antiemetic regimens for some chemotherapies previously considered only moderately emetogenic, and the increasing use of NK-1 inhibitors and/or olanzapine.[68]

Ondansetron effectively prevents nausea and vomiting in patients treated with highly emetogenic agents for acute leukemia or multiple myeloma (i.e., high-dose melphalan) or who are being prepared for bone marrow transplantation with cyclophosphamide and total-body irradiation.[67,69] In the transplantation recipients, 83% of patient-days were without any vomiting or retching, and in another 10%, there were no more than two emetic episodes. Ondansetron is also effective in preventing emesis induced by single- or multiple-fraction radiation therapy.[5] Ondansetron is as effective as high-dose metoclopramide in preventing nausea induced by cisplatin, cyclophosphamide alone, or doxorubicin chemotherapy.

Oral granisetron has shown equivalence to ondansetron in studies of patients receiving cisplatin- or carboplatin-based regimens. In patients receiving moderately emetogenic therapy, oral granisetron with dexamethasone was as effective as intravenous ondansetron and dexamethasone. Oral or intravenous granisetron and dexamethasone were effective in a bone marrow transplantation program in which patients were treated with Cytoxan and total-body irradiation, and these agents, along with oral prochlorperazine, were also effective in patients undergoing peripheral blood SCT for which patients received Cytoxan, VP-16 or thiotepa, and cisplatin. Granisetron is now available in an extended-release formulation for one-time subcutaneous administration on day 1 of chemotherapy.

Palonosetron is a second-generation 5-HT3 RA with higher potency, stronger receptor-binding activity, and longer half-life than the other drugs in this class.[5] Palonosetron 0.25 mg intravenously has been studied in moderately and highly emetogenic chemotherapy (MEC and HEC). Several subgroup analyses of the registrational noninferiority trials have been reported in which palonosetron was superior. Palonosetron has been identified as the preferred 5-HT3 RA in prevention of nausea and vomiting from moderately emetogenic regimens. Palonosetron is now available in an oral formulation along with netupitant, for single-day dosing on day 1 of MEC and HEC (to be given with oral steroids as well, with the steroid sometimes dosed orally on days 2 to 4 as well, depending on the emetogenicity of the regimen). Ondansetron and the other 5-HT3 RAs have far fewer side effects than high-dose metoclopramide. Reports of extrapyramidal reactions are rare,[5] and sedation, dystonic reactions, akathisia (e.g., severe restlessness, "ants-in-the-pants" feeling), and tardive dyskinesias do not occur. Patients can develop constipation, mild headache, QT prolongation, and elevated levels of transaminases.

Corticosteroids

The mechanism of the antiemetic action of corticosteroids remains undefined. Corticosteroids are effective when used alone to prevent emesis induced by agents of moderate or low emetogenic potential.[67,69] They are also a useful component of antiemetic therapy regimens that include ondansetron, granisetron, aprepitant, or metoclopramide and add efficacy in randomized controlled trials.[67,69]

The recommended specific corticosteroid drug, dose, and duration of therapy has not been determined. Dexamethasone and methylprednisolone are the best-studied agents, but no trials have demonstrated the superiority of one corticosteroid over another. Using anecdotal evidence recommendations for dexamethasone 4 to 8 mg orally (PO) two to three times per day, methylprednisolone 16 to 32 mg PO two to three times per day, or prednisone 20 to 30 mg PO two to three times per day have all been suggested. It is important to recognize that steroids are often part of the combination antiemetic regimens that have been shown effective in published trials, yet the steroid is often forgotten or omitted in real-world practice after day 1 of treatment; one should consult a published guideline and attend to whether an oral steroid should be prescribed on days 2 to 4 of the chosen antiemetic regimen.

Metoclopramide

Metoclopramide is a substituted benzamide that promotes gastric motility and reduces the emetic activity of chemotherapy agents by blocking dopamine receptors (at low-to-moderate doses) and 5-HT3 receptors (at high doses) in the chemoreceptor trigger zone. Because of a more favorable side effect profile, 5-HT3 antagonists have replaced high-dose metoclopramide. At lower doses (5 to 10 mg orally or intravenously every 6 hours) metoclopramide is useful in treating mild-to-moderate and delayed nausea and vomiting. Delivery of the drug on a schedule that maintains adequate levels during expected emesis appears to be important.

The side effects, which may be caused by the interaction of metoclopramide with dopamine receptors, can be quite troublesome. They include akathisia, dystonic reactions (age related), sedation, and diarrhea. Benzodiazepines such as lorazepam and β-blockers such as propranolol can prevent or reverse the akathisia, and diphenhydramine or benztropine can prevent or reverse the dystonias. However, these agents induce additional side effects, including dry mouth and sedation. Short-term, high-dose metoclopramide or long-term use at usual doses has been associated with persistent and disabling movement disorders, especially tardive dyskinesias.

Neurokinin-1 Inhibitors

Substance P can cause emesis, and it appears to play a role in chemotherapy-related nausea and vomiting. Its effects are mediated through NK-1 receptors.[5] Agents that cross the blood-brain barrier and inhibit NK-1 activity (e.g., aprepitant, netupitant) are more effective than a 5-HT3 RA and dexamethasone alone in moderating acute chemotherapy-related nausea and vomiting, and they are particularly effective in decreasing delayed nausea and vomiting occurring after HEC and MEC.[5,67] Aprepitant is an inhibitor of CYP3A4 and therefore may cause elevation of chemotherapy agents primarily metabolized by this route; however, these elevations are not considered clinically significant, and there are no recommended dose adjustments. Aprepitant can cause significant decreases in the prolongation of the international normalized ratio induced by warfarin and increases the area under the curve of dexamethasone. The maximum dose of dexamethasone in combination with aprepitant is 12 mg. Fosaprepitant, the intravenous prodrug of aprepitant, has demonstrated equivalent efficacy to the 3-day oral regimen as a single dose at 150 mg on day 1. Oral netupitant has been studied in HEC and MEC regimens as part of a single-dose combination product with oral palonosetron. These studies have demonstrated similar safety and efficacy when compared with combination antiemetic therapy including aprepitant.[70]

Olanzapine

Olanzapine has been shown to improve control of both acute and delayed nausea and vomiting in HEC and MEC when used in combination with dexamethasone and a 5-HT3 RA. Olanzapine is also shown to be superior to standard antiemetics in the breakthrough CINV setting.[71] Its primary side effect is sedation, and some evidence suggests that a 5 mg dose may be effective, with fewer side effects than the 10 mg dose.

Anticipatory Nausea and Vomiting

The treatment of ANV is best achieved through prevention with aggressive antiemetic therapy and treatment of anxiety with the appropriate agents (see "Benzodiazepines"). However, in patients for whom this approach has not been successful and in whom ANV develops, a variety of behavioral techniques have been helpful.[5] These include hypnosis, progressive muscle relaxation with guided imagery, systemic desensitization, and distraction. Results may be optimized if a therapist trained in these techniques works with the patient, but patients can use progressive muscle relaxation with guided imagery on their own.

Benzodiazepines

The benzodiazepine lorazepam has only mild antiemetic activity when used as a single agent. It is used frequently in the treatment and prevention of nausea and vomiting, particularly when anxiety is associated with the nausea and vomiting. It markedly decreases anxiety and the akathisia associated with metoclopramide therapy, and induces dose-related memory loss and marked sedation.

Cannabinoids

Currently only one pharmaceutical tetrahydrocannabinol-containing agent is available via prescription (Cesamet or nabilone has been discontinued in the US market). Dronabinol is FDA approved for the treatment of CINV. Synthetic cannabinoids are mostly reserved for patients with difficult-to-treat, refractory nausea and vomiting or as a rescue agent. Younger patients find cannabinoids more effective than do older patients, likely due to better tolerated side effects associated with the therapeutic doses of these agents. The cannabinoids cause ataxia, dry mouth, orthostatic hypotension and dizziness, euphoria (or dysphoria), and a feeling of being "high."[72]

Other Drugs

Other agents that are more active than placebo include the butyrophenones haloperidol and droperidol, and the phenothiazine prochlorperazine. These agents are less effective drugs than the agents previously mentioned, and all cause sedation. The butyrophenones produce dystonic reactions, akathisia, and occasionally hypotension. Scopolamine, a centrally acting anticholinergic, can be effective for patients with a vertiginous component to their nausea, but can also cause significant anticholinergic side effects. It is typically used as a topical medicated patch placed behind the ear, and is anecdotally more helpful in patients who have CINV and a history of motion sickness. Caution must be used when handling the patch, as it can transfer medication to the hands and then cause pupillary abnormalities if the eyes are rubbed, which may be mistaken as signs of a serious medical issue like a stroke.

CONCLUSION

Pain remains one of the most distressing and debilitating symptoms in patients with hematological disorders. Whether secondary to the disease process, iatrogenic, diagnostic, or therapeutic interventions, or related complications, pain is frequently underappreciated and undertreated. A methodological approach to evaluate and manage pain is recommended. Knowledge of the wide range of pharmacologic and nonpharmacological interventions is essential for the clinician managing pain. Pain refractory to standard approaches should be referred to pain or palliative care specialists.

Nausea and vomiting are common side effects of chemotherapy and should be treated aggressively to assure patient comfort during the treatment of their hematologic illness. Several targeted therapies exist and should be used based on the emetogenic potential of the agents used and the patient's clinical condition and comorbidities. Severe or refractory nausea should involve palliative care consultation.

ACKNOWLEDGMENTS

Many thanks to the prior authors of this chapter for their excellent work and their willingness to share its content for this version. This includes Dr. Janet Abrahm, as well as Drs. Shane E. Peterson, Kathy J. Selvaggi, Bridget Fowler Scullion, and Craig D. Blinderman.

CHAPTER 100

PALLIATIVE CARE

Kathleen A. Lee, Hilary McGuire, Barbara Reville, and Janet L. Abrahm

Palliative care for seriously ill children and adults is provided by an interdisciplinary team of clinicians who focus on communication about values and goals of care and ameliorating suffering from physical, social, spiritual, existential, and psychological concerns.[1] Members of the interdisciplinary palliative care team include registered and advanced practice nurses, physician assistants, social workers, pharmacists, chaplains, and adult and pediatric physicians, many of whom are ABIM certified in Hospice and Palliative Medicine. Palliative care teams augment rather than replace the active treatment of illness, striving to enhance patients' quality of life in concert with patient and family goals.

The Institute of Medicine (IOM) recommends improved access to palliative care, expanded education of all healthcare professionals in palliative care domains with an emphasis on communication, and expanded research in the areas of caregiver support, innovative payment models to incentivize team-based palliative care, and use of health information technology in care coordination and communication.[2]

Palliative care is not reserved for patients at the end of life; it should be available as well to patients of any age receiving curative or life-prolonging treatments.[2] Recent expert consensus practice guidelines, including those by the American Society of Clinical Oncology (ASCO), recommend palliative care concurrent with oncological care for patients with advanced cancer and/or high symptom burden.[3] Early palliative care integration alongside treatment of solid tumors improves patient quality of life and symptom management and may extend lives.[4] While palliative care subspecialists provide clinical support in more complex situations and palliative care education, innovation, and research, all clinicians should integrate high-quality palliative care into their care of patients with serious illness because there are not now nor in the future will there be enough palliative care providers to meet the need.[5]

National Comprehensive Cancer Network (NCCN) guidelines advise palliative care referral for patients with refractory or relapsing hematologic malignancies (HMs) and intractable cancer pain.[2] However, although patients living with HM and hematopoietic stem cell transplant (HSCT) have palliative care needs and an especially high symptom burden,[3,4] they are less likely than solid tumor patients to receive palliative care referrals.[5] Unique barriers to palliative care and hospice involvement in HM care include significant prognostic uncertainty related to many HM diagnoses and the benefit of palliative blood transfusions. HM patients are more likely to receive more aggressive measures (e.g., chemotherapy, hospital admissions, intensive care unit admissions) in the last 30 days of life and are less likely to enroll in hospice at the end of life.[6] Furthermore, many hematologic oncologists still view palliative care as end-of-life care.[7] HSCT physicians report concerns about palliative care specialists' lacking adequate knowledge about HSCT and that patients perceive a palliative care referral signifies the end of further cancer-directed therapies.[8]

This chapter reviews core elements of palliative care for children and adults, with specific attention to the growing understanding of palliative care needs in patients with HM/HSCT and newer models of palliative care integration within HM/HSCT care.

PEDIATRIC PALLIATIVE CARE: SPECIAL ISSUES

Pediatric palliative care is an emerging frontier in the comprehensive care of children. Specific issues related to palliative care for pediatric patients and their families include the following[13]:

- Because there are smaller numbers of dying children than adults, there are fewer palliative care pediatric professionals and children are under-represented in palliative care protocols.
- The heterogeneity of serious illnesses, many rare, requires the involvement of many disciplines and specialists in the palliative care team.
- Many children have genetic diseases, so there may be more than one affected child in a family.
- Pediatric palliative care may extend over years, even decades. A broad developmental spectrum is represented, including changes in the individual child through time.
- The underlying principles and ethics of how to care for patients with serious illness are universal across the lifespan. A child or adolescent diagnosis of life-threatening or life-limiting illness, however, throws an assumed sequence out of order. Children expect to care for dying parents. When parents instead find themselves watching their child face death, a sense of tragic absurdity prevails. Not only is time shortened, but its order is shattered. A child or adolescent with a life-threatening illness represents a premature separation from the family. Even before the child has become a differentiated individual through a natural developmental sequence, that child is wrenched away. When a psychological separation from parents has not yet been affected, the child and the parents have little preparation for the separation caused by death. The adolescent who is beginning to negotiate independent existence is often the hardest to face when that "moving forward" is irreversibly halted, or at least disrupted; a younger child has not even had the time to begin to form life goals.
- One of the foremost goals is to initiate palliative care proactively for children earlier in the illness trajectory, prioritizing the care of the family, with a particular focus on the young siblings. The timing of palliative care consultation and the clinical approach may differ depending on the prognosis for the child, the decisions that must be made in choosing treatment options, and the need for improved management of pain and suffering to provide optimal quality of life.

COMMUNICATION

Prognosis and Decision Making

Pediatric Population

Surveys of bereaved parents indicate that physician communication about prognosis is not optimal, and bereaved parents consider high-quality communication to be the most important element of quality physician care.[2] Compared with physicians, parents are overly optimistic about the child's chances of cure, and this is especially true when the prognosis is uncertain. Parents value clear information that is communicated sensitively and includes the child, when developmentally appropriate. Although they find prognostic information about their child upsetting, a majority of parents want as much information about the prognosis as possible.[9] Being aware of these beliefs may help physicians discuss the prognosis with greater frequency and clarity.

During the last decade, there has been increased recognition of the importance of the child's participation in making treatment decisions. Crucial to this process is an assessment of the child's or adolescent's ability to appreciate the nature and consequences of a specific medical decision. This becomes particularly complex when the wishes of the child differ from those of the parents. Because actual assessment tools are only in the early stages of development, professionals must rely exclusively on their clinical judgment to assess children's understanding of the contingencies they are facing. This is often a juncture when input from members of the interdisciplinary palliative care team can be crucial: children often express their understanding, awareness, and thoughts about treatment options and living or dying to individuals other than their parents or primary physician.

Adult Population

Similarly, adult patients living with serious illness and their families value clear information about the prognosis when communicated sensitively.

Although most patients report wanting prognostic information from their oncologist, patients with advanced refractory disease may not ask about their prognosis, and oncologists often do not initiate the discussion. In one recent observational study of HM patients after their first oncologic visit,[10] only half of the patients were told unambiguous prognostic estimates for mortality or cure. This is likely due in part to significant prognostic uncertainty associated with HM diagnoses.

When first diagnosed, HM patients often need to start treatment immediately. Though great advances in the treatment of adult HM have improved survival rates, the clinical courses of these diseases vary significantly from patient to patient. Some HM patients respond to curative treatment attempts with long-term remission and after a period of time are considered cured. Others have an initial response to curative-intended therapies only to relapse later at an unpredictable time; some then respond to further treatments for eventual remission while others succumb. For some unfortunate HM patients, their cancer is so advanced at the time of diagnosis that they experience a rapid clinical decline and die. This unpredictability of an HM patient's course can make decisions about when to stop cancer-directed therapies and when to start end-of-life therapies challenging.

Communication in Serious Illness: Strategies

Effective communication can allow clinical providers to align therapeutically with patients and family members. Discussing prognosis, breaking bad news, and discussing late goals of care with patients with advanced disease are all times when clinicians can demonstrate their commitment to an ongoing collaborative partnership. Conversations should demonstrate respect for cultural differences and the belief that psychosocial and spiritual growth can occur, even at the end of life. If these conversations are done well, they can lay the groundwork for further discussions about patients' hopes, fears, goals, values, and spiritual concerns as they make decisions about their medical care, including their thoughts about resuscitation and life-sustaining therapies. These conversations should be documented in the electronic medical record and recorded as a physician order when possible (e.g., in a Medical Order for Life sustaining Treatment [MOLST] or Physician Order for Life-Sustaining Treatment [POLST] form).[2]

Children with serious hematologic disorders have usually lived with the illness over months or years. Their knowledge, understanding, and awareness of their precarious life situation are often profound at physical, cognitive, and emotional levels. In the past, disclosure to the child of his or her prognosis (and even, in some instances, the diagnosis) was thought to be harmful.[11] Since the 1980s, there has been a shift toward open communication. To shield the child from the truth may only heighten anxiety and cause the child to feel isolated, lonely, and unsure of whom to trust.

Clinicians interested in improving their communication skills when caring for patients with serious illness can refer to online resources, such as the Center to Advance Palliative Care (capc.org), the Serious Illness Conversation Guide (https://www.ariadnelabs.org/areas-of-work/serious-illness-care/), and VitalTalk (vitaltalk.org). A few key communication skills strategies are described as follows.

Cultivating Prognostic Awareness

Even when patients are provided with clear statistical information about their prognosis by their oncologist, they may have an inaccurate impression of the goals of their treatment and of their prognosis. If they cannot process this difficult information, they are unlikely to be able to make appropriate personal or medical decisions.

Improving a patient's prognostic awareness is an important component of early palliative care. Using advanced communication techniques,[12] palliative care clinicians can facilitate patients' prognostic awareness, and support patients as they swing between hope and the nightmare of awareness of how serious their illness is. After improving a patient's prognostic awareness, palliative care clinicians can help patients with serious illnesses identify their hopes, values, and realistic goals.

Breaking Bad News

Table 100.1 contains an outline of the suggested steps to take when breaking bad news.[13] For patients with advanced disease, the goal is to establish or strengthen trust and reassure them that the clinician is committed to caring for them, even though their disease cannot be cured.

REMAP: A Framework to Facilitate Effective Late Goals of Care Conversations

Table 100.2 contains an outline of the suggested steps of REMAP, a technique useful for goals-of-care conversations with patients and/or family members when current treatments for the disease have not worked and the medical plan needs to be re-evaluated.[14]

TABLE 100.1 **Breaking Bad News**

1. Make yourself, the patient, and the family comfortable.
2. Find out what they know.
3. Indicate that you are planning to tell them something that is serious (give a "warning shot").
4. Find out whether they want to be told or whether they want someone else to be told.
5. Find out how much they want to know (i.e., the big picture versus all the details).
6. Tell them in words they can understand, allowing time for questions along the way (i.e., use less medical jargon).
7. Empathically respond to their emotions.
8. Let them know that this is only the first of many discussions with you.
9. Ask them to summarize what they heard you say; ask if they have further questions.
10. Arrange your next meeting with them.

Based on Abrahm JL. Update in palliative medicine and end-of-life care. *Annu Rev Med.* 2003;54:53; and Back A, et al. *Mastering Communication With Seriously Ill Patients: Balancing Honesty With Empathy and Hope.* New York: Cambridge University Press; 2009.

TABLE 100.2 **REMAP Framework for Late Goals of Care Conversations**

Reframe the situation: Explain that the status quo related to current medical plan is not working anymore. "We're in a different place."

Expect emotions: Talking begins to make this transition real.

Map values before talking about treatments or code status.

Align yourself with the patient's values-show that you heard.

Plan medical treatments that match your patient's values.

Caregiver Distress

Caregivers, whether close relatives or friends of the patient with an HM, suffer significant collateral distress in psychosocial, physical, financial, and informational domains during the course of their loved one's illness.[15] Emerging evidence shows parents, partners, relatives, and friends experience high levels of emotional distress and diminished quality of life at predictable illness milestones including diagnosis, onset of treatment toxicities, treatment regimen changes, and care transitions.[16]

The overlay of uncertainty about the future heightens both caregivers' stress level and sense of being out of control. The innate coping resources and social, psychological, and medical health of the caregiver are predictive of whether the caregiving experience will simply traumatize them or also be a source of personal growth. The interdisciplinary team should therefore assess caregivers' emotional health routinely and provide support and resources from diagnosis through survivorship. Integrating palliative care within HM teams to assess and support caregivers early in the treatment course led to reduced psychosocial distress and early identification of stress symptoms.[17,18] As novel treatment regimens shift from acute care to ambulatory settings, the impact on caregivers' efficacy, well-being, and sequelae will be an important variable of treatment outcomes and program development.[19]

RELIEF OF SUFFERING

Suffering includes physical, social, spiritual or existential, and psychological dimensions.

Management of Physical Distress in Children

Maintaining patient comfort is of critical importance throughout treatment, as well as during the end stages of life. Although effective pain control is a hallmark of palliative care, pain is only one of many distressing symptoms. The spectrum of physical symptoms includes (although it is not limited to) dyspnea, fatigue, seizures, loss of appetite, nausea and vomiting, constipation, and diarrhea. Early studies among bereaved parents of children who died of cancer indicate that optimal comfort is far from being achieved, even in major pediatric teaching centers.[20] Failure to relieve a child's end-of-life distress may have long-lasting implications for bereaved parents, who are negatively affected by the child's experience of pain years beyond the death.

Psychological symptoms such as depression and anxiety are also prevalent in children at the end of life. Children also experience existential concerns. Creating opportunities for communication around these sources of distress involves using creative strategies that incorporate the developmental stage of the child. Strategies may involve verbal communication using open-ended questions such as "What are you hoping for?" and "What are you worried about?"

However, many children communicate best through nonverbal means such as artwork and music. Children may be more willing to "talk things over" with puppets or stuffed animals rather than real people. Importantly, euphemistic expressions about death can be confusing or even frightening (for instance, equating death with sleep may result in the child's being afraid of going to bed).

Management of Physical Distress in Adults

Patients with HM experience a high physical symptom burden similar to patients with metastatic solid tumors, especially during treatment, when hospitalized, or when they develop advanced disease.[7] Intense HM treatment modalities (HSCT) and chimeric antigen receptor (CAR) T-cell therapy are likely to worsen an HM patient's existing symptom burden and neuropsychiatric outcomes.[7,21]

Pain management and antiemetic therapy for adults are reviewed elsewhere in this textbook (see Chapters 97, 99, and 110). Anxiety, depression, delirium, and control of symptoms occurring in the last days of life are reviewed later in this chapter.

Social Concerns

Among social sources of distress are financial concerns and, with increasing disability, loss of independence and decreasing sense of contribution to the family, work, or other pursuits. Worries about burdening the family or that the family will fail them when they really need them can lead patients to request Medical Aid in Dying. Social workers are key team members who can help alleviate or at least ameliorate these sources of distress and can help the caregivers cope. They can also assess and address the contributions to the distress of developmental issues, meaning and impact of the illness, the patient's coping style, the illness' impact on the patient's sense of self, relationships, stressors, economic, circumstances, and physician-patient relationships.

Spiritual Concerns

Clinicians should also explore a seriously ill patient's religious and spiritual concerns and understand what rituals will be important at the end of life. Spiritual and existential distress occurs when individuals are unable to find sources of meaning, hope, love, peace, comfort, strength, and connection in life, or when there is dissonance between their beliefs and what is happening to them. Patients who use "positive" religious coping (e.g., prayer, feeling a sense of connectedness to a religious community, having a positive relationship with a god) have been found to have better mental health status, growth in the spiritual dimension with stress, and a better overall quality of life than those with "negative" religious coping (e.g., ascribing their illness to a punishing god or one who has abandoned them).[22]

Psychological Concerns

Clinicians must assess and attend to patients' and families' psychological distress and must be able to distinguish normal human reactions of grief, sadness, despair, fear, anxiety, loss, and loneliness in patients living with serious illness from clinical anxiety and depression.

Anxiety and Depression

It is noteworthy that the symptoms of depression and anxiety are often not recognized in children and in many instances are inadequately addressed. Significant anxiety is found in approximately 25% of adult patients with cancer,[18] and anxiety symptoms can interfere with their ability to receive care. Patients with panic disorder, agitated depression, phobias, obsessive-compulsive disorder, delirium, post-traumatic stress disorder, or adjustment disorders can all present with anxiety. Anxiety in dying patients may arise from worries about the future (uncontrolled symptoms, family concerns, concerns about death), isolation from loved ones, metabolic abnormalities, withdrawal from alcohol, opioids, benzodiazepines, drug reactions (e.g., akathisia from metoclopramide, paradoxical agitation from benzodiazepines and olanzapine), and uncontrolled pain.

Non-pharmacological treatments, such as relaxation training, hypnosis, supportive psychotherapy, and counseling are very effective. Pharmacologic treatments usually include benzodiazepines (e.g., short-acting lorazepam, starting dose 0.5 to 2 mg every 8 hours orally [PO] or parenterally [IV] as needed; or long-acting clonazepam, starting dose 0.25 to 0.5 mg PO two times daily), selective serotonin reuptake inhibitors (SSRIs, see later), and when there is evidence of delirium, neuroleptics (see later).

It is estimated that 5% to 26% of patients with advanced cancer meet the criteria for major depressive disorder; patients with high symptom burden, such as patients facing HSCT, are at higher risk.[23] It can be difficult to discern which patients with advanced disease are grieving rather than being depressed. The usual somatic signs of depression are common in this population and are not helpful in making this distinction. Grieving patients are very sad, and tearful, but there are things that make them happy, and they look forward to the future. Depressed patients, however, have anhedonia and can feel worthless, guilty, hopeless, or helpless. Pain, a past or family history of substance abuse, depression, or bipolar illness are major risk factors for depression. When asked the screening question “Are you depressed?,” most seriously ill patients who respond “Yes” are very likely to be confirmed as depressed in a more comprehensive evaluation.

As part of depression treatment, pain must be brought under control. Counseling can explore patients’ fears, provide emotional support, and help patients review their lives and find meaning and areas of accomplishment in them. A variety of models of therapy are used, and none has been shown to be superior to others. The psychostimulants, dextroamphetamine, and methylphenidate (2.5 to 5 mg PO at 8 AM and noon; maximum dose 20 mg PO daily) often act within a few days. The SSRIs are the first choice when immediate onset is not needed because they usually take several weeks to show effect. Useful agents include citalopram (Celexa; 10 mg PO daily initially; maximum 40 mg PO daily); escitalopram (Lexapro; 10 mg PO daily initially; maximum 20 mg PO daily); sertraline (Zoloft; 50 mg PO daily initially, maximum 200 mg PO daily); fluoxetine (Prozac; 5 to 10 mg PO daily initially; maximum 50 mg PO daily); and the serotonin norepinephrine reuptake inhibitor venlafaxine (Effexor; 37.5 PO twice daily initially; maximum 225 mg PO daily). Venlafaxine inhibits norepinephrine serotonin and dopamine reuptake, and patients have severe withdrawal symptoms if it is stopped abruptly. Major side effects of the SSRIs include hyponatremia, sexual dysfunction or loss of libido, and gastrointestinal complaints (e.g., nausea, diarrhea, foul-smelling flatus). Modafinil may reduce SSRI-related sedation. The exact mechanism of action of mirtazapine (Remeron; 15 mg PO at bedtime initially; maximum 45 mg PO at bedtime) is unknown.

If the patient is expected to live longer than weeks to a few months, a stimulant and an SSRI should be started simultaneously. The stimulant can then be titrated off several weeks later. Tricyclic antidepressants are less useful in these patients because of their side effect profile.

If the patient does not respond to first-line agents, a psychiatrist should be consulted. Referral to a psychiatrist is also necessary when the psychiatric diagnosis is unclear.

Delirium

Delirium occurs in up to 80% of patients dying from advanced cancer and can cause distress and anxiety for caregivers.[20] Delirious patients can be agitated, hypo-active, or vacillate between the two. Symptoms of delirium include insomnia and daytime somnolence, nightmares, restlessness or agitation, irritability, distractibility, hyper-sensitivity to light and sound, anxiety, difficulty in concentrating or marshalling thoughts, fleeting delusions, hallucinations, emotional lability, attention deficits, and memory disturbances.

Validated delirium screening severity tools are available, but comprehensive psychiatric evaluation is recommended to exclude other disorders, such as anxiety, depression, anger, dementia, or psychosis. The cause of delirium is often never determined and frequently multi-factorial. Medications, especially opioids, H2-blockers, high dose corticosteroids, and use of multiple anti-cholinergic agents commonly contribute. Opioid-induced central nervous system toxicities are more common in patients with renal dysfunction, on high doses of opioids for longer durations, with impaired cognition before starting the opioids, with dehydration, or taking other psychoactive drugs. Other causes include metabolic abnormalities (hypercalcemia, hyperglycemia, or uremia), malnutrition, hypoxia, fever, infection, uncontrolled pain, hepatic failure, primary brain tumor, and brain metastases.

Treatment for delirium should begin while the underlying causes are being treated. In addition to the medications listed in Table 100.3, it is helpful to make the patient’s surroundings as familiar as possible,

TABLE 100.3 **Treatment of Delirium (Adult Patient)**

Drug	Dose	Comment
Typical and Atypical Antipsychotics		
Haloperidol	1–4 mg PO, or 0.5–2 mg SQ, IV qhs or bid to tid	Do not exceed 20 mg in 24 h
Quetiapine	25–200 mg PO qhs	Particularly useful in elderly patients with evening delirium Start 25 mg qhs for 3–4 days
Olanzapine	2.5–5 mg PO/SL/IV	Start 2.5–5 mg PO/SL/IV qhs to bid (2.5 mg for elderly patients); can use q4–6 h prn agitation Maintain the patient on the effective dose (divided into a bid dose), then taper over 2 weeks, as tolerated; also antiemetic
Aripiprazole	5 mg PO qd	Do not exceed 30 mg Does not prolong and may shorten QTc
Chlorpromazine	12.5–1000 mg PO/IV/PR	Sedating; may cause significant hypotension
Benzodiazepines*		
Lorazepam	0.5–1 mg PO/IV q1–2 h 5–10 mg PO bid	Avoid using alone (i.e., without an antipsychotic) for patients with a hyperactive delirium
Diazepam	5–10 mg PO bid	Useful PR for patients unable to take oral medication
Clonazepam	0.5–5 mg PO/SL bid to tid	Tablets have been used PR for terminal delirium; do not exceed 20 mg/24 h
Midazolam	30–100 mg IV / SQ over 24 h	IV drip or subcutaneous infusion for terminal delirium

*Caution: Any benzodiazepine may exacerbate delirium, especially in older adults (>70 years of age).

bid, Twice a day; *d*, day; *hs*, at bedtime; *IM*, intramuscularly; *IV*, intravenously; *PO*, orally; *PR*, rectally; *prn*, as needed; *q*, every; *SL*, sublingual; *SQ*, subcutaneously; *tid*, three times a day.

restore aids to hearing and sight if they are needed, re-orient the patient frequently, and have family members, friends, or well-known caregivers present.

MANAGEMENT CONCERNS DURING THE LAST DAYS OF LIFE

Children

Children with advanced cancer who receive concurrent home-based palliative care have improved quality of life at the end of life and are more likely to die at home. Families can plan ahead and choose a setting for their child's death: home, hospice, or hospital, with their child's input. Clear information about how the child is likely to die and professional support to validate the family's choice are crucial. Even more important is the explicit stated "permission" from all members of the professional team that the family may change their choice freely at any time, that all options remain open, and that no decision is irrevocable. In the past, siblings were rarely included in these discussions and were often inadequately prepared for the eventuality of a child dying at home. Recently, however, their voices are beginning to be heard.

Adults

Common physical symptoms that occur in the last weeks before an adult's death from cancer include pain, noisy or moist breathing, urinary incontinence or retention, dyspnea, and nausea and vomiting. Patients may also experience fatigue. Hunger and thirst are unusual. Treatments for problems at the end of life are reviewed in Table 100.4. Patient and family wishes and options about the setting for end-of-life care should be explored. Some evidence suggests that patients with cancer who die at home have better quality of life and that their caregivers have better bereavement outcomes than cancer patients who die in the hospital. Given the potentially high symptom burden of HM patients in the final moments of life, such as severe bleeding or dyspnea, more patients with HM die in the hospital and are less likely to be enrolled in hospice services (discussed further later).

HOSPICE PROGRAMS

Table 100.5 contains a detailed comparison of palliative care and hospice programs. Hospice programs focus on providing end-of-life care to patients with a prognosis of 6 months or less (for adults). Hospice enrollment improves the quality of life for patients with advanced cancer and reduces the risk of depression for caregivers. In the United States, the four levels of hospice care include: (1) home care, the most common setting; (2) respite care, during which patients can be admitted to a nursing home or hospice house for brief periods each month to provide respite for the family caregivers; (3) continuous crisis care, in which hospice nurses/staff provide intensive continuous (often symptom management) care in the home; and (4) general inpatient hospice ("GIP"), requiring frequent adjustment of parenteral medications for intensive symptom control that cannot be managed in another care setting (GIP is typically given in a hospice facility or hospital setting). The Medicare Hospice benefit does not require a "do not resuscitate" status, but it does require that the attending physician and the Hospice medical director certify that the patient has a prognosis of 6 months or less to live if the disease follows its usual course.

Despite the clear benefits of hospice care among cancer patients, patients with HM have the lowest rates of enrollment. When patients with HM do enroll, they are more likely to do so within days of death than are patients with non-hematological malignancies. Though multiple factors exist for low and late hospice use in this population, a significant barrier is limited access to blood transfusions in hospice programs because of cost and logistical concerns. Since transfusion dependence is common in patients with blood cancers, recent efforts have advocated for combining palliative transfusions with hospice services in efforts to optimize end-of-life care for patients with HM.[19]

TABLE 100.4 **Treatment of Common Problems in the Final Days (Adult Patient)**

Problem	Agent(s)	Routes, Doses
Baseline pain	Concentrated oxycodone or morphine solution Morphine or hydromorphone tablets Fentanyl[a] Methadone liquid Acetaminophen, naproxen Dexamethasone	PO/SL q4h around the clock; individualized PR q4h; individualized Transdermal; individualized PO, per gastric tube, individualized PO, PR tid to qid PO, PR (requires compounding) daily to bid
Breakthrough pain	Concentrated oxycodone or morphine solution Fentanyl[a]	PO or per gastric tube q4h around the clock; individualized Transmucosal (buccal, sublingual); individualized
Excessive oropharyngeal secretions "Noisy breathing"	Scopolamine Hyoscyamine Glycopyrrolate Atropine	Scopolamine Transderm Scop patch 1mgq3 days 0.125–0.25mg SL tid to qid 0.2–0.4 mg IV tid to qid or 1–2 mg PO bid to tid 0.4 mg SL, IV q4–6 h
Dyspnea (anxiety)	Lorazepam Chlorpromazine	1 mg PO, SL, q2–4 h; IV q1–2 h 25 mg PO, PR q4–12 h; or 12.5 mg IV q4–8 h
Dyspnea (other)	Morphine	10–15 mg SL oral concentrate q4h
Nausea	Combinations of lorazepam, metoclopramide, dexamethasone, and/or haloperidol	PR q6h; compounded suppositories with desired agents (depending on presumed cause of nausea)
Anxiety	Lorazepam Diazepam suppository	1 mg PO, SL, q2–4 h; IV q1–2 h 5–10 mg PR daily
Delirium	Haloperidol Olanzapine	2–4 mg PO, SQ, IV q30 min prn (max 20 mg/24 h) 2.5–5mg PO, SL/IV qhs to bid plus PRN q4h

[a] Fentanyl only for opioid tolerant patients.

All liquid PO medications can be given per gastric tube.

h, Hour; *IV*, intravenously; *PO*, orally; *PR*, rectally; *PRN*, as needed; *q*, every; *qhs*, nightly at bedtime; *qid*, four times a day; *SL*, sublingually; *tid*, three times a day.

Modified from Abrahm JL. *A Physician's Guide to Pain and Symptom Management in Cancer Patients.* 3rd ed. Baltimore: Johns Hopkins University Press; 2014.

Notably, many children are not referred to hospice because their illness experience is inconsistent with hospice specifications: their prognosis is uncertain; there is a blending of goals, which can result in more costly health care; and providers lack pediatric expertise. Importantly, the Patient Protection and Affordable Care Act now requires state Medicaid programs to allow children (under the age of 21) with a life-limiting illness to receive both Hospice care and

TABLE 100.5 Specialty Level Palliative Care Versus Hospice Care

Palliative Care	Hospice Care
Interdisciplinary Model of Care	**Interdisciplinary Program of Care**
Clinical specialty, offers expert: Symptom management and communication Psychosocial and spiritual care Inpatient, outpatient, and home care consultations to the primary team Coordination of care among treating teams	Medicare Hospice benefit, delivers: Symptom management and communication All medications needed for the terminal illness; DME; oxygen Psychosocial and spiritual care Home, inpatient, or respite care in a nursing home/hospice facility under the direction of the patient's physician delivered by the interdisciplinary hospice team Continuity with referring care team Bereavement care for a year after the death
Eligibility	**Eligibility**
Any patient with serious or life-threatening illness Any stage of the illness Concurrent with curative or disease-directed therapies	Estimated 6 months or less prognosis. Eligible for Medicare or secondary insurance. Some free care is available Focus is quality of life, rather than life prolongation
Interdisciplinary Consult Team	**Interdisciplinary Hospice Care Team**
Core team: Palliative care physicians, advanced practice nurses, physician assistants, registered nurses, social workers, chaplains, pharmacists. Encouraged: art, music, and massage therapists	Hospice medical director (physician), advanced practice nurses, physician assistants, registered nurses, social workers, home health aides, chaplains, volunteers, Administrative personnel, medical consultants, occupational therapists, physical therapists, speech therapists, and bereavement counselors. Encouraged: art, music, and massage therapists

curatives treatments concurrently (Section 2302, "Concurrent Care for Children" Requirement, CCCR). The full effect of this change remains to be seen.

BEREAVEMENT

Bereavement follow-up by the hospice or palliative care team is an intrinsic component of comprehensive pediatric palliative care. Many families expressed feeling a double loss: loss of their child and loss of their oncology team whom they have known and trusted, often over months and years. Parental grief has been recognized as more intense and longer lasting and other types of grief. Contact from a team member after the child's death can lessen the family's sense of abandonment and the palliative care team can serve a crucial preventive role by identifying families at particular risk for prolonged grief disorder and identifying resources for them.

Each bereaved person's loss is unique, but many people manifest similar symptoms of grief, and some of which become less persistent as they rebuild their lives. Recurrent intense symptoms typically occur at the anniversary of the patient's death but can occur at unpredictable times, induced by reminders of the deceased. Survivors appreciate calls or letters from the patient's physicians and nurses. For patients enrolled in Hospice programs, a formal bereavement program is offered for the family throughout the first year after the patient dies. After the formal program ends, the bereaved are welcome to continue to participate in any bereavement activities that have been meaningful to them.

At the time of death, survivors may seem numb, confused, or dazed. By the second month after the death, yearning predominates. During the next months, disbelief, depressed mood, and yearning decline gradually, and by 6 months after the death, most people have accepted its reality and are beginning to think about re-engaging in relationships and work, discovering new meaning and purpose. Siblings are especially vulnerable in the year following a child's death. By a year or 2, most survivors are accommodated to their loss. They become aware of the changes that must be made if they are to resume old relationships and responsibilities or to establish new ones and risk recurrent loss.

However, about 10% to 20% of survivors suffer either from depression or from a symptom complex previously called complicated grief, now identified as prolonged grief disorder.[20] Those with depression manifest symptoms of sadness, anhedonia, and psychomotor retardation but they are not yearning for the deceased or unable to accept the death. Depressed survivors benefit from counseling and consideration of pharmacologic treatment. Bereaved persons with prolonged grief disorder, in contrast, have grief symptoms that last beyond 6 months and cause functional impairments. Such patients are at increased risk for medical and psychiatric illness and should be referred for psychiatric or spiritual counseling. Persons at higher risk for the disorder include those with a history of attachment disorders, aversion to lifestyle changes, being unprepared for the death and unsupported afterward, and having a particularly interdependent relationship with the deceased.

Likely because of the treatment intensity and high symptom burden, parents of children who received HSCT reported higher levels of depression, anxiety, and stress compared to parents of children with HM who did not receive HSCT; those parents whose children died in the hospital after receipt of HSCT had a greater likelihood of meeting the criteria for prolonged grief disorder.[24] Though caregivers of both pediatric and adult patients with HM experience significant stressors during their loved one's illness which could increase the risk of developing prolonged grief disorder, there is currently a lack of studies focusing on the bereavement of family members of adult patients who die of HM.

CONCLUSION AND FUTURE DIRECTIONS

Palliative Care Integration with Hematologic Malignancy Care

Patients with HM and their families face unique challenges compared with patients with solid tumors. These challenges include the need to undergo high risk, intensive treatments with significant symptom burden, and prolonged hospitalization to achieve cure; times of high infection risk; significant prognostic uncertainty; difficult decisions about the benefits and burdens of continuing transfusion products when the prognosis of the cancer is weeks to months; increased likelihood of receiving more aggressive care in the last month of life; and increased likelihood of dying in the hospital.

Encouragingly, there is growing evidence that palliative care integration into the care of patients with HM and those receiving HSCT is achievable and can improve patient and family outcomes.[22,25]

Recent evidence suggests that HSCT recipients in both pediatric and adult settings benefit from collaborative efforts between HSCT and palliative care services, particularly when initiated early in the transplantation course.[22,26] With transparent communication, respect for roles, and a collaborative approach, HSCT and palliative care can collectively provide high-quality, multidisciplinary care for these highly vulnerable patients and their families.[24,26] Various pediatric models of palliative care and HSCT care exist to meet the differing needs of individual settings. In all, the incorporation of palliative care in HSCT does not change the focus of therapy or the goals of care. Rather, palliative care involvement provides an extra layer of support for HM/HSCT patients and their families, helping them hold their concurrent goals of cure/remission while maintaining their hope to live as well as possible.[26–29]

Adult inpatient integrated HM/HSCT/palliative care models are aimed at building collaboration and improving HM/HSCT providers' perceptions of palliative care. In a quality improvement project, Selvaggi et al. showed the feasibility of a specialty palliative team integration model that was well-received by hematologic oncologists within an HM/HSCT inpatient unit.[30] In a single-center randomized controlled trial of HM patients admitted for HSCT, after 2 weeks, those receiving inpatient palliative care concurrently with standard transplant care had less decrease in quality of life, decreased anxiety, less increase in depression, and less increase in overall symptom burden.[22]

Because HSCT patients experience a high burden suffering from both physical and emotional symptoms, patient and caregiver outcomes can be improved with early palliative care involvement.[18,19] To address this need, starting in September 2018 at Brigham and Women's Hospital/Dana Farber Cancer Institute (BWH/DFCI), we instituted a pilot "HemePal" quality improvement project. HemePal was an integrated palliative care co-rounding model that helped the inpatient BWH/DFCI bone marrow transplant physician assistant (PA) team control patient symptoms. A palliative care specialist (physician or nurse practitioner) co-rounded with the team once weekly. They also communicated daily with the PA team to identify patients needing more palliative care assistance for symptom management, which was provided either by "curbside" recommendations or a full consultation. This co-rounding model provided both palliative care specialists and the HM/HSCT providers an invaluable opportunity to learn from each other's perspectives and to build collaborative relationships to improve HSCT patients' care. Data evaluating the efficacy of this model is in process.

Though the benefits of PC integration within inpatient HSCT/HM care are known,[22] more research is needed to characterize the symptom burden of HM patients at all points in their illness trajectories and to evaluate further integrated palliative care interventions within this population.

CHAPTER 101

THERAPY-RELATED LATE EFFECTS OF HEMATOLOGIC MALIGNANCIES

Wendy Landier and Smita Bhatia

The past several decades have seen a marked improvement in survival for patients with hematologic malignancies. The 5-year survival is as follows: leukemia, 66%; Hodgkin lymphoma (HL), 89%; non-Hodgkin lymphoma (NHL), 75%; and multiple myeloma (MM), 54%. As a consequence, the population of long-term cancer survivors continues to grow. As of January 1, 2019, there were 451,700 leukemia survivors living in the United States, 234,890 HL survivors, and 757,710 NHL survivors.[1,2]

Attendant with this success is an increasing awareness of the occurrence of long-term morbidity and mortality associated with the very treatments responsible for the improvement in survival. The subject of long-term morbidity suffered by cancer survivors has been the topic of numerous reports. These reports demonstrate that survivors are at risk for developing adverse outcomes, including premature death, subsequent neoplasms, organ dysfunction (e.g., cardiac, pulmonary, gonadal), reduced growth, decreased fertility, impaired intellectual function, difficulties obtaining employment and insurance, and overall reduced quality of life.

Hematopoietic cell transplantation (HCT) is the treatment of choice for patients with hematologic malignancies experiencing disease recurrence after conventional regimens and for those with disease characteristics associated with poor prognosis if treated with conventional chemotherapy and radiation regimens. Complications observed after HCT often have a multifactorial origin encompassing issues related to prior cancer therapy, intensity of the preparative regimen, graft-versus-host disease (GVHD), and other posttransplantation complications.

This chapter summarizes select adverse outcomes among individuals treated for hematologic malignancies with conventional therapy alone or with HCT. Recommendations for providing ongoing follow-up care to this population are also reviewed.

CARDIOVASCULAR DISEASE

One of the more serious adverse events encountered in survivors of hematologic malignancies is late-occurring cardiovascular disease (CVD), which include arterial disease (coronary artery disease [CAD]: myocardial infarction, atherosclerotic heart disease, and angina pectoris; and cerebrovascular disease [stroke]) and cardiac disease (cardiomyopathy and congestive heart failure [CHF], valvular heart disease (VHD), conduction abnormalities, and constrictive pericarditis). These complications are more common than expected,[3,4] and often occur at an earlier age than observed in the general population.[5–7]

Mediastinal radiotherapy (RT) is associated with an increased risk of CAD, VHD, and CHF. Anthracycline chemotherapy increases the risks of VHD and CHF. Anthracyclines are directly toxic to the myocardium through a variety of mechanisms, including free radical-mediated oxidative damage and induction of cellular apoptosis. Joint effects of mediastinal RT, anthracyclines, and smoking appear to be additive.[8] Outcome is poor, with less than 50% of patients surviving 5 years after a diagnosis of CHF.[9]

Among adult-onset HL survivors, the risk of CVD increases with heart radiation dose and cumulative anthracycline dose.[10,11] Throughout their lives, HL survivors treated as adolescents or adults are at high risk for CVD. For patients treated before 25 years of age, the cumulative incidence at 60 years or older is 20%, 31%, and 11% for CAD, VHD, and CHF as first events, respectively.

Cardiac Disease

The anthracycline class of drugs is a well-known cause of late-onset cardiomyopathy leading to CHF. There is a strong dose-dependent relation between anthracycline exposure and risk of CHF. Among childhood cancer survivors, the incidence of CHF is less than 5% with cumulative anthracycline exposure of less than 250 mg/m^2, approaches 10% at doses between 250 mg/m^2 and 600 mg/m^2, and exceeds 30% for doses higher than 600 mg/m^2.[12–14] However, cumulative anthracycline exposure as low as 101 to 150 mg/m^2 may be associated with a 3.9-fold increased risk for cardiomyopathy when compared with those unexposed to anthracyclines.[15]

Among adult-onset cancer survivors, the 5-year cumulative risk of CHF is 10%.[16] The incidence of CHF has been estimated to exceed 25% with a dosage of 550 mg/m^2.[17] Among survivors older than 65 years of age, the risk of late-onset CHF is 29% higher among those exposed to doxorubicin, compared with those not treated with doxorubicin, and an increase in the number of cycles of doxorubicin-containing chemotherapy is significantly associated with increasing risk of CHF.[18]

Among blood or marrow transplant (BMT) recipients, the risk of CHF is highest after autologous BMT, approaching 10% at 15 years after BMT; (21976673) autologous BMT survivors are at a nearly fivefold higher risk of CHF when compared with age- and sex-matched individuals from the general population. The risk of late-occurring CHF is primarily due to pre-BMT exposure to anthracyclines.[4,9] Doxorubicin dose $\geq$300 mg/m^2 and cardiac RT dose greater than 30 Gy are independent risk factors for left ventricular (LV) systolic dysfunction.[19]

Young age at exposure is a significant modifier of anthracycline-related cardiotoxicity.[20] Females treated in childhood are at greater risk of developing doxorubicin-induced ventricular dysfunction.[12] The combined use of doxorubicin and chest radiation has been associated with a greater risk of late cardiac toxicity than either treatment given alone.[21,22] The presence of one or more conventional cardiovascular risk factors (CVRFs; diabetes, dyslipidemia, and hypertension) has a significant effect on the incidence of heart disease among HL survivors and NHL survivors.[18,21,23] The risk of post-BMT anthracycline-related cardiotoxicity also increases significantly among individuals with one or more conventional cardiac risk factors.[3,4,24,25]

Arterial Disease

Chest radiation produces intimal thickening of the coronary arteries and microvascular damage that causes reduced myocardial perfusion. Patients who received mediastinal radiation for HL have an increased risk of CAD compared with the general population.[26–28]

The risk of radiation-related CAD is generally higher among men and among younger patients. The risk of deaths related to myocardial infarction is 2.5-fold higher among HL patients when compared with an age- and sex-matched general population; the increased risk of myocardial infarction mortality persisted through to 25 years after first treatment. Risks are increased for patients treated with supradiaphragmatic radiation, anthracyclines, or vincristine. Among those exposed to supra-diaphragmatic radiation and vincristine and followed for ≥20 years after first treatment, the risk is 15-fold that of the general population.[29]

Using medically ascertained data, the cumulative burden metric was used to compare chronic cardiovascular health conditions among childhood HL survivors and general population controls. At 50 years of age, the cumulative incidence of survivors experiencing at least one grade 3 to 5 cardiovascular condition was 45.5%. The survivor cohort experienced, on average, 430 grade 1 to 5 and 101 grade 3 to 5 cardiovascular conditions per 100 survivors. At age 50, the grade 1 to 5 and 3 to 5 cumulative burdens in community-controls were appreciably lower at 227/100 and 17.0/100, respectively. Myocardial infarction and structural heart defects were the major contributors to the excess grade 3 to 5 cumulative burden among survivors. Higher cardiac radiation dose (≥35 Gy) was associated with higher grade 3 to 5 cardiovascular burden.[30]

Arterial disease in the transplant setting is related to accelerated atherosclerosis, attributed to pre-BMT and conditioning-related RT, and is compounded by the presence of CVRFs in the early post-BMT period.[24,31] The cumulative incidence of arterial events such as CAD or stroke among allogeneic BMT recipients is 10% at 15 years and the risk exceeds 20% at 20 years.[6,7] In this population, the median age at first myocardial infarction is as low as 53 years (range: 35 to 66),[25,32] which is earlier than would be expected for the general population (67 years)[33] or that reported in survivors of autologous BMT (61 years).[25,32] The risk of developing CVRFs is higher in allogeneic BMT recipients when compared with autologous BMT recipients, as well as age- and sex-matched general population.[25,34] The 10-year cumulative incidence of hypertension, diabetes, and dyslipidemia in allogeneic BMT recipients is 38%, 18%, and 47%, respectively; the risk for multiple (>2) CVRFs approaches 40% (compared with 26% in autologous BMT survivors). Conditioning with total body irradiation (TBI) has been associated with an increased risk of dyslipidemia and diabetes in survivors of BMT.[25,34] Abdominal RT possibly contributes to insulin resistance and/or metabolic syndrome, suggesting a role for radiation-induced pancreatic or hepatic injury.[35] The increased risk of diabetes and dyslipidemia among BMT survivors with prior exposure to TBI could potentially be due to the combined effects of abdominal RT and post-BMT gonadal dysfunction.[36]

Prevention of Cardiotoxicity

Given the known cardiovascular complications of cancer therapy, prevention of CVD is a focus of active investigation. There is strong evidence for dexrazoxane as a cardioprotectant. Dexrazoxane decreases oxygen free radicals through intracellular iron chelation.[37] In two meta-analyses, dexrazoxane was associated with 60% to 80% fewer clinical and subclinical cardiac events during and after anthracycline-based therapy.[38,39] Overall, toxicity and measures of tumor response were similar between patients exposed and unexposed to dexrazoxane.[38] Currently, the Food and Drug Administration approves dexrazoxane for women with metastatic breast cancer who have received 300 mg/m^2 of doxorubicin and who need additional anthracycline-based therapy. The American Society of Clinical Oncology also recommends considering dexrazoxane for adults with any history of cancer who have already received 300 mg/m^2 of doxorubicin-based therapy.[40]

Intermediate or surrogate endpoints (cardiac troponin T) in randomized clinical trials show that dexrazoxane reduces cardiotoxicity in children exposed to anthracyclines.[33,41,42] Longer-term follow-up data demonstrate that various echocardiographic indices of LV structure and function are worse in those not receiving dexrazoxane.[41] Girls benefit from dexrazoxane more than boys, particularly with respect to changes in the LV end-diastolic thickness-to-dimension ratio, a marker of pathologic LV remodeling. Further, there is no impact on late mortality among HL patients randomized to dexrazoxane.[43] However, comprehensive longer-term follow-up is required to document that dexrazoxane does indeed have a cardioprotective effect while maintaining comparable event-free survival.[43,44]

Liposome-encapsulated anthracyclines have been explored, using the premise that liposome-encapsulated anthracyclines escape the capillaries with wide endothelial gaps in the tumor, thus reaching high concentrations in the interstitial fluid of the tumor bed, but are less likely to escape the tight capillary junctions of the heart. Biopsy results have confirmed the relative safety in clinical use.[45,46] Data on the potential cardioprotection associated with liposomal formulations of anthracyclines is limited. A phase I study of liposomal daunorubicin in 48 children reported no cardioprotection.[47] A primary cardioprotection strategy (angiotensin-converting enzyme inhibitors and/or beta blockers as well as liposomal doxorubicin) in NHL patients with a high risk of anthracycline cardiotoxicity was found to result in fewer events (cardiovascular mortality and heart failure occurrence) when compared with historical controls.[48]

Specific recommendations for monitoring have been developed for childhood cancer survivors (http://www.survivorshipguidelines.org)[49,50] as well as for survivors of adult-onset cancer[51] and BMT (Table 101.1).[52]

PULMONARY EFFECTS

Pulmonary function compromise has been reported after conventional therapy in survivors of hematologic malignancies.[5,53–55] Pulmonary function abnormalities include reductions in total lung capacity (TLC), forced vital capacity (FVC), forced expiratory volume in the first second of expiration (FEV$_1$), and gas transfer (diffusing capacity of lung for carbon monoxide [DLCO]), suggesting obstructive and restrictive defects. Risk factors include exposure to certain chemotherapeutic agents (particularly bleomycin), radiation to the chest, underlying lung disease, female sex, and a younger age at exposure to the pulmonary-toxic therapeutic agents. Patients present with chronic cough, emphysema, lung fibrosis, oxygen requirements, and recurrent pneumonia. The cumulative incidence of any pulmonary disease after 35 years of follow-up exceeds 20% in childhood cancer survivors.[56] Childhood cancer survivors are 6.5-fold more likely to develop restrictive disease and 5.2-fold more likely to develop diffusion abnormalities when compared with healthy noncancer controls. Higher radiation dose (>20 Gy) and younger age at exposure (<16 years) is associated with restrictive disease. Female sex and higher chest radiation dose are associated with diffusion abnormalities. Over a period of 5 years, diffusion capacity declines among females and those exposed to high doses of chest radiation.[57]

Pulmonary complications, both infectious and noninfectious, are common after BMT. Multiple factors are thought to contribute to pulmonary complications in this population, including the type and duration of immunological defects produced by the underlying disease and treatment, the development of chronic GVHD, and the conditioning regimens employed. These complications are classified as early or late, depending on whether they occur before or after 100 days from transplantation. Early noninfectious pulmonary complications typically include pulmonary edema, upper airway complications, diffuse alveolar hemorrhage, and pleural effusion. Bronchiolitis obliterans occurs later after BMT. Idiopathic pneumonia syndrome, GVHD, and radiation-induced lung injury can occur in the early or late periods after BMT (reviewed in Khurshid and Anderson).[58]

The following pulmonary function tests are noted to decline after BMT: FEV$_1$/FVC, forced mid-expiratory flow, TLC, DLCO, residual volume (RV), functional residual capacity, and RV/TLC. Older age at allogeneic BMT is associated with lower FEV$_1$/FVC and DLCO, and higher RV/TLC. Bronchiolitis obliterans syndrome is a progressive, insidious lung disease occurring after allogeneic BMT and results in progressive circumferential fibrosis and ultimate cicatrization of the small terminal airways, manifesting as new fixed airflow obstruction (reviewed in Williams et al.).[59–64] Bronchiolitis obliterans has a strong correlation with chronic GVHD and has been reported in up to 6% of BMT recipients.[59] Most patients present when the degree

TABLE 101.1 Monitoring for Potential Late Effects

Potential Late Effects	Therapeutic Exposure	Recommended Monitoring	Suggested Interventions
Adverse psychosocial effects (e.g., depression, anxiety, posttraumatic stress disorder, limitations in healthcare access, relationship problems, risky behaviors, psychosocial disability due to pain, sleep problems, fatigue)	Diagnosis and treatment for hematologic malignancy	Clinical interview: yearly	Psychologic or social work consultation if indicated
Dental abnormalities (abnormal tooth development, increased susceptibility to caries and gum disease)	Chemotherapy Cranial irradiation TBI	Dental examination: every 6 months	Professional dental cleaning every 6 months; use of fluoridated toothpaste; topical fluoride applications as indicated; Panorex radiograph before orthodontic or dental procedures for patients treated before completion of tooth development
Peripheral neuropathy Raynaud phenomenon	Vincristine Vinblastine	Neurologic examination if symptomatic	Physical therapy if indicated; advise patient to protect against precipitating factors (e.g., cold environment)
Neurocognitive deficits	Methotrexate (intrathecal, high-dose systemic) Cytarabine (high-dose systemic) Cranial irradiation TBI	Formal neuropsychologic testing: baseline on entry to long-term follow-up; repeat as clinically indicated if evidence of impaired performance Clinical interview yearly, including assessment of educational and vocational progress	Referral for specialized educational services, curricular modifications, or vocational training programs if indicated
Clinical leukoencephalopathy	Methotrexate (intrathecal, high-dose systemic) Cranial irradiation	Clinical evaluation: yearly Brain MRI or CT if clinically indicated	Neurology consultation if clinically indicated
Cataracts	Corticosteroids Busulfan Cranial irradiation TBI	Funduscopic examination and visual acuity evaluation: yearly Ophthalmologic examination: yearly	Ophthalmology consultation if abnormalities detected
Xerophthalmia	Chronic GVHD related to HCT	History and eye examination yearly	Artificial tears, ophthalmology consultation if indicated
Xerostomia	Cranial irradiation Chronic GVHD related to HCT	Dental evaluation: every 6 months	Meticulous oral hygiene Artificial saliva products if indicated
Hearing loss	Platinum chemotherapy Aminoglycoside antibiotics Cranial irradiation	History and physical examination: yearly Audiogram: every 2–5 years for survivors who received platinum chemotherapy and/or cranial radiation dose $\geq$ 30 Gy	Audiology consultation if indicated
Hypothyroidism Thyroid nodules Thyroid malignancy	Cranial, cervical, spinal, mantle, or mediastinal irradiation; TBI	Free T_4, TSH, thyroid examination: yearly	Endocrine or surgical referral as indicated
Cardiomyopathy Arrhythmias Subclinical left ventricular dysfunction	Anthracyclines Chest or thoracic irradiation (e.g., mantle, mediastinal)	Detailed history of exertional tolerance (e.g., dyspnea on exertion, chest pain): yearly ECG (for evaluation of QT interval): baseline on entry into long-term follow-up; ECHO: Every 2–5 years as indicated based on age at therapy and total anthracycline or radiation dose	Cardiology consultation if indicated; additional cardiology evaluation of patients who are pregnant or planning to become pregnant if patient received $\geq$ 250 mg/m^2 of an anthracycline, radiation dose $\geq$ 35 Gy, or any dose of anthracycline combined with radiation $\geq$ 15 Gy
Pericarditis Pericardial fibrosis Valvular disease Premature atherosclerotic heart disease	Chest or thoracic irradiation (e.g., mantle, mediastinal)	Consider cardiology consultation 5–10 years after irradiation to evaluate risk for coronary artery disease in patients who received doses $\geq$35 Gy or $\geq$15 Gy plus anthracyclines. Optimize cardiovascular risk factors, including blood pressure, lipid profile, and blood glucose.	Cardiology consultation if indicated; additional cardiology evaluation in patients who are pregnant or planning to become pregnant if patient received $\geq$ 250 mg/m^2 anthracycline, anthracycline combined with radiation $\geq$15 Gy, or radiation dose $\geq$35 Gy

TABLE 101.1 **Monitoring for Potential Late Effects—cont'd**

Potential Late Effects	Therapeutic Exposure	Recommended Monitoring	Suggested Interventions
Pulmonary dysfunction (fibrosis, interstitial pneumonitis)	Bleomycin Busulfan Chest/thoracic irradiation TBI Chronic GVHD related to HCT	Pulmonary function testing: baseline at entry into long-term follow-up and as clinically indicated for patients with progressive dysfunction	Pulmonary consultation for symptomatic patients; influenza and pneumococcal vaccine; counsel patients to avoid smoking and avoid SCUBA diving
Thrombosis Vascular insufficiency Infection of retained cuff or line tract	Central venous catheter	History and physical examination: yearly as clinically indicated	Surgical referral as indicated
Hepatic dysfunction	Mercaptopurine, thioguanine, methotrexate (systemic), abdominal radiation, HCT	ALT, AST, bilirubin: baseline on entry into long-term follow-up; repeat if clinically indicated	If abnormal results for baseline studies, obtain prothrombin time (to assess hepatic synthetic function) and viral hepatitis screening
Chronic viral hepatitis	Blood products	Hepatitis C antibody and HCV RNA by PCR: once if transfused before universal screening of blood supply (1992 in the United States) Hepatitis B surface antigen and core antibody: once if transfused before universal screening of blood supply (1972 in the United States)	Gastroenterology or hepatology consultation and annual AFP for patients with chronic hepatitis; hepatitis A and B immunizations in patients lacking immunity
HIV infection	Blood products	HIV-1 and HIV-2 antibodies: once if transfused before universal screening of blood supply (1985 in the United States)	Infectious disease consultation for patients with confirmed infection
Life-threatening infection	Splenectomy Abdominal/splenic radiation ≥ 40 Gy Chronic active GVHD	Physical examination at time of febrile illness to evaluate degree of illness and for potential source of infection	Counsel patients regarding risk of life-threatening infections and indication for medical alert bracelet. Administer parenteral antibiotics and continue close medical observation in patients with temperature ≥ 38.3°C (101°F) or other signs of serious infection; immunize with pneumococcal, meningococcal, and HIB vaccines
Iron overload	HCT (and patients requiring multiple red blood cell transfusions)	Serum ferritin: at entry into long-term follow-up	If abnormal, consider chelation, or repeat as clinically indicated until within normal limits
Bowel obstruction Chronic enterocolitis Fistulas and strictures	Abdominal surgery Abdominal or pelvic irradiation Chronic GVHD related to HCT (esophageal strictures, vaginal stenosis)	History and physical examination: yearly and as clinically indicated Serum protein and albumin levels: yearly in patients with chronic diarrhea or fistula	Surgical and gastroenterology consultations as clinically indicated
Renal insufficiency	TBI Abdominal or splenic irradiation Ifosfamide Platinum chemotherapy	Blood pressure: yearly BUN, creatinine, electrolytes, calcium, magnesium, phosphorus baseline and repeat as clinically indicated	Nephrology consultation for proteinuria, hypertension, progressive renal insufficiency
Hemorrhagic cystitis Bladder fibrosis Dysfunctional voiding Bladder malignancy	Cyclophosphamide Ifosfamide Irradiation of abdomen, pelvis, iliac, inguinal sites	Voiding history: yearly	Urinalysis and urology consultation as clinically indicated for incontinence, dysfunctional voiding, macroscopic hematuria (culture negative)
Growth hormone deficiency	Cranial irradiation TBI	Height, weight: every 6 months during puberty until growth is complete Obtain bone age in poorly growing children	Endocrine referral for patients failing to follow normal growth curve

Continued

TABLE 101.1 Monitoring for Potential Late Effects—cont'd

Potential Late Effects	Therapeutic Exposure	Recommended Monitoring	Suggested Interventions
Overweight/obesity	Cranial irradiation	BP, growth percentile, BMI: yearly	Endocrine referral as indicated
Dyslipidemia	TBI	Lipid profile every 2 years	
Hypogonadism/Infertility	Alkylating agents Cranial irradiation Abdominal or pelvic irradiation Testicular irradiation Spinal irradiation > 25 Gy TBI	Menstrual history, sexual function, height, weight: yearly Pubertal history, Tanner stage: yearly until maturity	FSH, estradiol: (females); Testosterone: (males); for failure of pubertal progression or clinical symptoms of estrogen or testosterone deficiency Semen analysis: as indicated or requested by patient. Endocrine referral for hypogonadal patients (for hormone-replacement therapy); reproductive endocrinology referral for patients desiring evaluation of fertility options
Precocious puberty	Cranial irradiation	Physical examination, height, weight, Tanner stage: yearly until maturity LH, FSH, estradiol (females), or LH, FSH, testosterone (males): as clinically indicated in patients with accelerated pubertal progression Obtain bone age in rapidly growing prepubertal children	Endocrine referral as indicated for accelerated puberty (<age 8 years in females, <age 9 years in males)
Adverse pregnancy outcomes (e.g., spontaneous abortion, premature delivery, low-birthweight infant)	Irradiation of abdomen, pelvis, iliac, inguinal, paraaortic sites TBI	History: yearly and as clinically indicated	High-risk obstetric care
Osteopenia, osteoporosis	Corticosteroids Methotrexate (high-dose systemic) HCT	Bone-density study (DXA scan): baseline at entry into long-term follow-up, repeat as clinically indicated	Calcium and vitamin D supplementation; weight-bearing exercise; treatment of exacerbating conditions (e.g., hypogonadism); consider pharmacologic intervention (e.g., bisphosphonates)
Avascular necrosis	Corticosteroids Methotrexate (systemic) HCT	History: yearly; MRI if clinically indicated	Orthopedic consultation if indicated
Scoliosis/kyphosis	Irradiation of trunk (e.g., mantle, spine, abdomen, pelvis)	Physical examination of spine: yearly (every 6 months during pubertal growth spurt) Radiologic imaging of the spine if clinical evidence of scoliosis or kyphosis	Orthopedic referral
Joint contractures	Chronic GVHD related to HCT	Physical examination yearly	Orthopedic referral if indicated
Chronic infection	Chronic GVHD related to HCT	History: yearly	Prophylactic anti-infective agents; infectious disease consultation if indicated
Vitiligo Scleroderma Joint contractures Nail dysplasia Dysplastic nevi Skin cancer Secondary benign or malignant neoplasms in radiation field	Chronic GVHD related to HCT Irradiation (any field)	Physical examination: yearly Inspection and palpation of irradiated skin and soft tissues: yearly	Dermatology or rehabilitation consultation if clinically indicated Dermatology or surgical referral and radiographs if indicated for any suspicious lesions
Bone malignancies Brain tumor	Cranial irradiation	History and physical examination: yearly Neurologic exam: yearly	Neurosurgical consultation as indicated
Breast cancer	Chest or axillary radiation TBI	Clinical breast examination: yearly beginning at puberty until age 25, then every 6 months Mammogram and breast MRI: yearly beginning at age 25 or 8 years after irradiation (whichever comes last)	Teach breast self-examination; instruct patient to perform monthly self-examination beginning at puberty and report changes immediately; surgical consultation if clinically indicated

Continued

TABLE 101.1 **Monitoring for Potential Late Effects—cont'd**

Potential Late Effects	Therapeutic Exposure	Recommended Monitoring	Suggested Interventions
Gastrointestinal malignancy	Abdominal, pelvic, spinal irradiation, TBI	Colonoscopy every 5 years beginning 5 years after radiation or at age 30, whichever occurs last; more frequently as clinically indicated; or multitarget stool DNA test every 3 years; other options may be considered based on informed decision-making between patient and provider	Surgical consultation if indicated
AML (preceding myelodysplastic phase associated with alkylating agents)	Anthracyclines Epipodophyllotoxins Alkylating agents Stem cell priming with etoposide Autologous transplantation for NHL or Hodgkin lymphoma	Physical examination: yearly for 10 years after therapy CBC and differential and bone marrow evaluation if clinically indicated	Counsel patient to report fatigue, bruising, bleeding, bone pain

AFP, α-Fetoprotein; *ALT*, alanine aminotransferase; *AML*, acute myeloid leukemia; *AST*, aspartate aminotransferase; *BMI*, body mass index; *BP*, blood pressure; *BUN*, blood urea nitrogen; *CBC*, complete blood cell count; *CT*, computed tomography; *DXA*, dual-energy X-ray absorptiometry; *ECG*, electrocardiogram; *ECHO*, echocardiogram; *FSH*, follicle-stimulating hormone; *GFR*, glomerular filtration rate; *GVHD*, graft-versus-host disease; *HCT*, hematopoietic cell transplantation; *HCV*, hepatitis C virus; hemoglobin A1c, glycosylated hemoglobin; *HIB*, *Haemophilus influenzae* type B; *HIV*, human immunodeficiency virus; *LH*, luteinizing hormone; *MRI*, magnetic resonance imaging; *NHL*, non-Hodgkin lymphoma; *PCR*, polymerase chain reaction; *RNA*, ribonucleic acid; T_4, thyroxine; *TBI*, total body irradiation; *TSH*, thyroid-stimulating protein.
Modified from Children's Oncology Group: *Long-term follow-up guidelines for survivors of childhood, adolescent, and young adult cancers*, version 5.0, 2018, Children's Oncology Group. http://www.survivorshipguidelines.org

of airflow is severe, causing significant dyspnea on exertion and a persistent nonproductive cough. Lung biopsy findings demonstrating damage to the bronchiolar epithelium, obliteration of bronchiolar lumens, inflammation between the epithelium and the smooth muscle, and pulmonary fibrosis are characteristic. The National Institutes of Health definition of bronchiolitis obliterans requires the following: (1) absence of active infection, (2) decreased FEV_1 (<75% of predicted value), (3) evidence of airway obstruction with a ratio of FEV_1 to FVC of less than 0.7, (4) elevated RV of air (>120% of predicted normal), or (5) an expiratory chest computed tomographic (CT) scan or lung biopsy that reveals air trapping or bronchiectasis. Recommended therapy includes high-dose systemic steroids for a protracted course, with or without the addition of other immune suppressants.[64] Leukotriene inhibitors have emerged as a potential therapy because of the elevated levels of leukotrienes implicated in bronchiolitis obliterans. Late-onset severe restrictive lung defect is also observed after allogeneic BMT, usually ~3 months post-BMT. Major CT findings include pleuroparenchymal thickening with volume loss, and evidence for fibrosis, predominantly in upper lobes–a finding that is consistent with pleuroparenchymal fibroelastosis. Other findings include interstitial pneumonia. Pulmonary function tests reveal diffusion capacity abnormalities.[65]

Specific recommendations for monitoring for pulmonary complications have been developed for childhood cancer survivors (http://www.survivorshipguidelines.org)[49] and for survivors of BMT (see Table 101.1).[66,67]

ENDOCRINOLOGIC EFFECTS

Thyroid

Patients with hematologic malignancies treated with cranial, craniospinal, or mantle irradiation are at increased risk for thyroid complications. Among survivors of HL, and to a lesser extent leukemia, abnormalities of the thyroid gland, including hypothyroidism, hyperthyroidism, and thyroid neoplasms, have been reported to occur at rates significantly higher than those found in the general population.[68] Hypothyroidism is the most common nonmalignant late effect involving the thyroid gland. Survivors of HL are at particularly increased risk; after exposure to radiation at doses of 30 to 45 Gy to the thyroid gland the cumulative incidence of hypothyroidism is 30% at 20 years, with the cumulative incidence increasing to 50% for radiation doses above 45 Gy.[69] Hyperthyroidism is infrequently seen, but is also associated with a history of neck radiation.[69] Thyroid nodules are common in patients treated with neck radiation for HL, but the majority of these do not undergo malignant transformation.[70]

Monitoring for survivors at risk for thyroid complications is reviewed in Table 101.1.[69]

Obesity

An increased prevalence of obesity has been reported among survivors of childhood ALL.[71,72] In an analysis from the Childhood Cancer Survivor Study, Oeffinger et al.[73] compared the distribution of the body mass index (BMI) of 1765 adult survivors of childhood ALL with that of 2565 adult siblings of childhood cancer survivors. Survivors were significantly more likely to be overweight (BMI of 25 to <30) or obese (BMI ≥30). Risk factors for obesity were cranial irradiation, female sex, and age 0 to 4 years at diagnosis of leukemia. Females diagnosed under the age of 4 years who received a cranial radiation dose of more than 20 Gy were found to have a 3.8-fold increased risk for obesity. In a recent report of survivors of standard-risk childhood ALL treated without cranial radiation, there was no increased risk of overweight or obesity compared with general population health data.[74] Obesity has the potential to adversely impact the overall health status in survivors and is associated with insulin resistance, diabetes mellitus, hypertension, and dyslipidemia. Yearly monitoring of BMI is recommended (see Table 101.1).

Gonadal Dysfunction

Treatment-related gonadal dysfunction has been well documented in male and female patients after therapy for hematologic malignancies and there is a reasonable body of research that provides a basis for counseling patients regarding the long-term gonadal effects of radiation and chemotherapy.

Radiation effects on the ovary are age and dose dependent. The ovaries are particularly sensitive to radiation, and it has been estimated that there is a 50% depletion in oocytes after exposure of the ovaries to 2 Gy,[75] and premature menopause is associated with even low doses of ovarian radiation.[76] The majority of females who receive ovarian radiation doses greater than 20 Gy develop acute ovarian failure; at lower radiation doses, post-pubertal adolescent and adult women are more susceptible to acute ovarian failure than are pre-pubertal girls.[77] Spinal irradiation for the treatment of childhood leukemia appears to result in clinically significant ovarian damage in some survivors,[78] and cranial irradiation in young girls is associated with an increased risk for premature puberty.[79]

The effects of radiation on testicular function, including germ cell number and Leydig cell function, have been investigated. Reduced sperm production has been observed after testicular doses of 1 to 6 Gy and follows a dose-dependent pattern.[80] Azoospermia has been reported among HL patients with calculated testicular irradiation exposures ranging from 1 to 3 Gy, which may be reversible.[81] Testicular doses between 4 to 6 Gy have been associated with prolonged azoospermia and decreased testicular volume, whereas doses greater than 6 to 8 Gy are associated with irreversible injury.[81] Spermatogenesis is impaired in 75% to 100% of male childhood HL survivors in whom radiation and chemotherapy were combined.[82] Most pre-pubertal males treated with fractionated radiation doses less than 12 Gy to the testis will undergo normal pubertal maturation. Males treated for testicular leukemia with radiation doses greater than 20 Gy who pre- or peri-pubertal are at high risk of delayed sexual maturation as well as significant germ cell depletion. In males who have reached puberty and undergo testicular radiation, only about 50% develop Leydig cell failure at doses greater than 30 Gy.[80]

Ovarian and testicular damage can also result from chemotherapeutic agents, with alkylating agents showing the strongest association. Effects of chemotherapy on gonadal function are typically sex-, age-, and dose-dependent. Ovarian dysfunction has been well documented in HL patients treated with alkylating agents, singly or in combination (e.g., MOPP regimen consisting of mechlorethamine, vincristine [Oncovin], procarbazine, and prednisolone, or a COPP regimen consisting of cyclophosphamide, vincristine [Oncovin], procarbazine, and prednisolone).[83] MOPP and COPP regimens have been reported to result in azoospermia in more than 90% of exposed males, with a negative correlation seen between cumulative doses of alkylating agents and sperm concentration.[84] Even with a reduction in the dose of cyclophosphamide in the hybrid COPP/adriamycin, bleomycin, and vinblastine (ABV) regimen for HL, the majority of young males are infertile, likely due to the procarbazine component in this regimen.[85] In a study of 6224 male survivors of childhood cancer between 15 and 44 years of age, those with a diagnosis of hematologic malignancy were significantly less likely to sire a pregnancy compared with sibling controls; those with a diagnosis of HL were least likely to sire a pregnancy (RR of fertility: 0.34; 95% confidence interval [CI]: 0.28–0.41), followed by NHL (RR: 0.60; 95% CI: 0.48–0.74), and leukemia (RR: 0.70; 95% CI: 0.59–0.84); $P < .001$ for all comparisons.[81]

Young boys and adolescent males with aplastic anemia who receive standard-dose cyclophosphamide alone (200 mg/kg) as the pretransplant conditioning regimen appear to retain normal Leydig cell function, as do males who receive busulfan and cyclophosphamide, with normal plasma concentrations of luteinizing hormone and testosterone, and normal progression through puberty.[86] Semen analyses have been normal in approximately two-thirds of men after high-dose cyclophosphamide and several men have fathered normal children. Men treated with TBI-based regimens who have not received prior testicular irradiation generally retain normal Leydig cell function, regardless of their age at treatment.[87] Germ cell dysfunction occurs in all men treated with TBI-based regimens and azoospermia is the rule; however, some younger males (age <25years at HCT) without chronic GVHD have showed some degree of spermatogenesis following standard-dose TBI.[88]

The effect of alkylating agents alone on ovarian function in females is dependent upon dose and age at exposure.[76] Females treated with busulfan and cyclophosphamide are at very high risk for ovarian failure and premature menopause, and procarbazine is also particularly gonadotoxic.[89] The outcome of ovarian function after TBI appears to be determined by the age at exposure. Approximately 50% of prepubertal girls receiving fractionated TBI enter puberty spontaneously and premature ovarian failure is seen in all patients who are older than 10 years of age when treated with TBI.[86] Pregnancies among survivors who received TBI are at an increased risk for spontaneous abortion, premature labor, and low-birthweight offspring.[90]

Monitoring for gonadal dysfunction is reviewed in Table 101.1.[80,91]

MUSCULOSKELETAL EFFECTS

Osteonecrosis is a painful and debilitating condition that develops when the blood supply to the bone is disrupted, usually in areas of terminal circulation. The condition is believed to be the result of vascular compromise with resultant death of bone and cell tissues or disruption of bone-repair mechanisms.[92] Osteonecrosis has been reported after conventional therapy for hematologic malignancies, particularly after exposure to dexamethasone between the ages of 10 and 20 years. This complication usually develops during or shortly after completion of therapy but may progress over time.[93]

Osteonecrosis is increasingly being reported among HCT recipients.[94,95] Campbell et al.[96] conducted a retrospective cohort study and described the cumulative incidence of osteonecrosis to be 2.9% among autologous HCT recipients, 5.4% among allogeneic HCT recipients, and 15% among unrelated donor HCT recipients. Among allogeneic HCT recipients, male sex, presence of chronic GVHD, and exposure to cyclosporine, tacrolimus, prednisone, and mycophenolate mofetil rendered patients at increased risk, in particular among patients with a history of exposure to three or more drugs. The mean latency period was 18 months. The hip joint was the most commonly involved joint (80%); however, the knee, wrist, and ankle joints were also affected. The cumulative incidence of surgery (mainly arthroplasty) approached 31% at 1 year from osteonecrosis diagnosis. Li et al.[95] conducted a case-control study of children who underwent allogeneic HCT and found that children at highest risk included those who underwent transplant during the period of rapid pubertal growth and those who received myeloablative conditioning and immunosuppression for treatment of GVHD.

Osteopenia (bone density 1 to 2.5 standard deviations below mean) or osteoporosis (bone density >2.5 standard deviations below mean) is commonly seen in survivors of hematologic malignancies.[69,97] Risk factors include therapy with corticosteroids, methotrexate (at higher doses), and cranial irradiation with resultant pituitary insufficiency or gonadal dysfunction. Survivors of HCT are also at increased risk for reduced bone mineral density; identified risk factors in these patients include treatment with corticosteroids for chronic GVHD, prior cranial irradiation (resulting in growth hormone deficiency), and gonadal failure.[86] Lifestyle factors that increase the risk for osteopenia include lack of regular weight-bearing exercise, inadequate calcium and vitamin D intake, smoking, and excessive alcohol consumption.[98]

Detection and diagnosis of musculoskeletal sequelae depend largely on anticipating these issues in vulnerable hosts, on taking a careful history, and on performing a thorough physical examination. Monitoring recommendations are reviewed in Table 101.1.[49,52]

COGNITIVE IMPAIRMENT

Cognitive impairment affects over 10 million cancer survivors in the US. Cognitive impairment can range from subtle to severe and last for months or years after treatment. Many survivors of hematologic malignancies also experience memory loss, distractibility, and difficulty performing multiple tasks. These patients may also concurrently suffer from mood disturbances and symptoms including fatigue and pain; these may compromise their ability to function adequately.[99] Decreased cognitive function is associated with poorer quality of life, inability to achieve work and educational goals, inability to drive or read, and decreased social connectedness (reviewed in Williams et al., 2016[100]). There is evidence to suggest that impaired working memory and executive functioning is prevalent in older patients with hematologic malignancies and may have an impact on survival.[101]

Many non-therapy-related factors can influence cognition in patients with a hematological malignancy. These include demographics (e.g., age and cognitive reserve) and comorbidities (physical comorbidities, as well as anxiety, depression, and fatigue). Cancer and its treatment may exacerbate normal aging and increase cognitive impairment in the cancer survivors.[102] A National Health and Nutrition Examination Survey (NHANES) analysis showed that survivors aged 60 years and older scored worse on a test of processing speed, attention, working memory, and executive function domains compared to non-cancer survivors.[103] Non-neurotoxic exposures, such as thoracic radiation, can adversely impact survivors' cognitive function through chronic conditions. Management of chronic diseases may mitigate neurocognitive outcomes among aging survivors of childhood cancer.[104] Cognitive impairment and its downstream effects become a major issue in survivors of hematological malignancies, given that many of these diagnoses are more common in older patients.

Cranial radiation has long been associated with cognitive impairment in childhood cancer survivors,[105–107] although antimetabolite chemotherapy and corticosteroids have also been implicated as potential contributors.[108–111] Additional risk factors include higher treatment intensity, younger age at treatment exposure, and female sex.[109,112–116] Cognitive deficits usually become evident within 1 to 2 years following cranial radiation and are progressive in nature. The decline over time is typically reflective of the child's failure to acquire new abilities or information at a rate similar to peers, rather than because of a progressive loss of skills and knowledge. The cognitive problems seen in childhood ALL survivors are generally characterized by reduced attention, processing speed, executive function and global intellectual function.[114] Affected children with information-processing deficits exhibit academic difficulties and are prone to problems with receptive and expressive language, attention span, and visual and perceptual motor skills. The deficits observed after chemotherapy alone are restricted to attention, executive function, and complex fine-motor functioning; global intellectual function is relatively preserved. Cognitive function in long-term survivors of childhood cancer appears particularly vulnerable to the effects of fatigue and sleep disruption.[117,118] The cognitive impairment observed in survivors of childhood ALL persists into adulthood; this impairment is associated with reduced educational attainment and unemployment,[119] and challenges with independent living, and health care use.[120]

A meta-analysis of existing evidence for the mechanisms underlying changes in the central nervous system (CNS) and cognitive function in ALL survivors after treatment compared with controls found that ALL survivors develop: (i) cognitive sequelae in intelligence, academics, attention, memory, processing speed, and executive function domains; (ii) decreased grey and white matter volume in cortical and several subcortical brain regions, with functional changes particularly in frontal regions and the hippocampus; (iii) cognitive impairments related to CNS changes; and (iv) reduction, but not resolution, of late cognitive sequelae in patients in whom prophylactic irradiation was replaced by systemic/intrathecal chemotherapy. Thus, ALL survivors treated with chemotherapy alone perform worse in processing speed, verbal selective reminding, and academics and display significant IQ deficits of 6 to 8 points compared with population norms but perform better than survivors treated with cranial RT on verbal selective reminding, processing speed, and memory span.[111,121]

A spectrum of neuropathological syndromes related to leukoencephalopathy may occur in survivors of childhood hematologic malignancies, including radionecrosis, necrotizing leukoencephalopathy, mineralizing microangiopathy and dystrophic calcification, cerebellar sclerosis, and spinal cord dysfunction, manifesting clinically as ataxia, spasticity, dysarthria, hemiparesis, or seizures. Leukoencephalopathy has been primarily associated with methotrexate-induced injury of white matter. However, cranial irradiation may play an additive role through disruption of the blood-brain barrier, allowing greater exposure of the brain to systemic therapy.[122] Acute leukoencephalopathy during chemotherapy treatment without cranial radiation for childhood ALL predicts higher risk for long-term neurobehavioral problems. Survivors of ALL may benefit from preventative cognitive and/or behavioral interventions, particularly those who develop acute leukoencephalopathy.[123]

Long-term survivors of HL may also be at risk for cognitive impairment. HL survivors followed for an average of 10 to 15 years from diagnosis show impaired cognitive functioning, with reduced attention, memory, processing speed, and executive function.[124] The cognitive impairment is associated with radiologic indices suggestive of reduced brain integrity and occurs in the presence of symptoms of cardiopulmonary dysfunction.[125]

NHL is a heterogeneous group of diseases with diverse treatments including radiation, immunotherapy, and chemotherapy. Adult survivors of childhood NHL experience impaired neurocognitive function, which is associated with lower social attainment and poor health-related quality of life (HRQOL).[126] Small studies of adult-onset B-cell NHL survivors find a higher prevalence of self-endorsed cognitive problems when compared with the general population. The domains affected include attention and executive function. The 18- to 59-year-olds endorse more problems than the 60- to 85-year-olds.[127,128] Treatment of primary CNS lymphoma with cranial radiation and high-dose methotrexate has resulted in median overall survivals that exceed 5 years.[129] Longitudinal studies in this population indicate that although there is some recovery over time, cognitive impairment does persist in the domains of attention, executive function, verbal fluency, memory, and psychomotor function 5 years or more after treatment.[130–132]

BMT survivors are at risk for cognitive impairment. Among adults undergoing BMT, myeloablative allogeneic BMT recipients showed significant cognitive decline compared with healthy controls. Reduced-intensity allogeneic BMT recipients showed evidence of delayed decline. Cognitive functioning in autologous BMT recipients is generally spared. Older age, male sex, and lower education, income, and cognitive reserve are associated with post-BMT cognitive impairment. At 3 years post-BMT, global cognitive impairment is present in 19% of autologous and 36% of allogeneic BMT recipients.[133] BMT recipients endorse more cognitive problems at all timepoints when compared with healthy controls. Fatigue is associated with greater endorsement of cognitive problems at 1 year after BMT. Overall, there is a modest correlation between self-endorsed cognitive problems and objective cognitive impairment. Higher self-endorsed cognitive problems are associated with higher odds of not returning to work at 3 years after BMT. These findings suggest that self-endorsed cognitive problems can identify vulnerable patient subpopulations in need of detailed cognitive assessment and possible cognitive remediation.[134]

There is emerging interest in attempting to understand whether interpatient variability in cognitive outcomes can be explained by polymorphisms in candidate genes conferring susceptibility to cognitive decline. Among childhood cancer survivors, inferior cognitive or behavioral outcomes have been associated with polymorphisms in genes related to oxidative stress (*NOS3*, *SLCO2A1*) and/or neuroinflammation (*COMT*).[135] Among BMT recipients, after adjusting for BMT type, age at BMT, sex, race/ethnicity, and cognitive reserve, SNPs in the blood-brain barrier, telomere homeostasis, and DNA repair genes are significantly associated with cognitive impairment. Inclusion of candidate genetic variants enhances the prediction of risk of post-BMT cognitive impairment beyond that offered by demographic/clinical characteristics and represents a step toward a personalized approach to managing patients at high risk for cognitive impairment after BMT.[136]

Monitoring recommendations for cognitive dysfunction are reviewed in Table 101.1.[49,52]

Psychosocial Effects

Treatment for hematologic malignancies may result in adverse psychosocial effects, including mental health disorders, such as anxiety, depression, and posttraumatic stress; psychosocial disability due to pain, sleep problems, and fatigue; relationship problems; fear of recurrence; and limitations in healthcare access (see Table 101.1). Survivors of HL reported more impairments in physical (particularly fatigue), professional, and cognitive domains, as well as more financial limitations, when compared with age-matched healthy controls.[124] In NHL survivors, treatment-related neurocognitive impairment (related to cranial radiation, intrathecal chemotherapy, and high-dose methotrexate and cytarabine), was found to be associated with lower educational attainment, occupational status, and unemployment.[126] In those with diffuse large B-cell lymphoma, younger survivors (18 to 59 years of age) were found to have more financial and social functioning problems compared with the normative population; however, in older survivors the proportion experiencing these problems was comparable to that reported by the normative population.[128] Survivors of primary CNS lymphoma treated with high-dose methotrexate and whole-brain radiation were more likely to report poorer self-perceived quality of life outcomes compared with survivors treated without radiation.[130]

Monitoring for psychosocial adverse effects of cancer treatment in survivors of hematologic malignancies should include a yearly clinical interview, with referral for psychologic or social work consultation if problems are identified.

OTHER TOXICITIES

Ocular Effects

Survivors of hematologic malignancies are at risk for the development of cataracts as a consequence of therapy with corticosteroids,[137] cranial irradiation,[138] TBI,[139] or busulfan.[140] In a cohort of childhood ALL survivors who were treated with chemotherapy with or without cranial radiation and received a mean cumulative prednisone equivalent dose of 5.2 gm/m^2, cumulative incidence of cataracts was 26 ± 8.1% at 25 years; cranial radiation was the only significant risk factor.[137] Belkacemi et al.[141] studied 1063 patients who underwent HCT for acute leukemia; the overall 10-year incidence of cataracts in this group of patients was 50%. Single-dose TBI was associated with a 60% incidence of cataracts, fractionated TBI was associated with a 43% incidence for those receiving six or fewer fractions, and a 7% incidence was reported for those receiving more than six fractions. Factors independently associated with an increased risk for cataract formation in this cohort were older age (>23 years), allogeneic bone marrow transplantation, higher dose rate (>0.04 Gy/min), and steroid administration for longer than 100 days. Xerophthalmia may also occur as a late complication because of decreased lacrimation resulting from damage to the lacrimal gland during radiation or, in HCT patients, from chronic GVHD.[142] Westeneng et al.[142] followed 101 adults up to 24 months after allogeneic HCT and reported ocular GVHD in 54% of patients, manifesting mainly as xerophthalmia and conjunctivitis; blepharitis and uveitis were encountered less often. Tabbara et al.[143] reported major ocular complications in 13% of 620 patients (age range: 9 to 65 years) after allogeneic HCT; complications included chronic ocular GVHD, corneal ulcers, cataracts, glaucoma, cytomegalovirus retinitis, fungal endophthalmitis, and the acquisition of allergic conjunctivitis from atopic donors.

Audiologic Effects

Survivors of hematologic malignancies who received platinum chemotherapy, those who had cranial irradiation at a young age (especially during infancy), and those who required supportive therapy with aminoglycoside antibiotics are at risk for therapy-related hearing loss.[144] Hearing loss associated with ototoxic agents is generally sensorineural in origin and is usually irreversible. Although a low incidence of hearing loss has been reported in survivors of HCT performed in childhood, the risk is elevated threefold to fourfold over that in the general population.[145] Data are beginning to emerge regarding genetic polymorphisms associated with increased susceptibility to platinum-related hearing loss; these data may prove useful in identifying future patients who are at increased risk for hearing loss as a consequence of platinum-based chemotherapy.[146]

Second and Subsequent Neoplasms

Second or subsequent neoplasms are defined as histologically distinct cancers developing after the occurrence of a first cancer. Subsequent neoplasms are conventionally categorized into two major types: therapy-related myelodysplastic syndrome/acute myeloid leukemia (t-MDS/AML) and solid tumors. The latency between diagnosis of the primary cancer and development of t-MDS/AML is generally short, whereas solid tumors have a longer latency, and the risk continues to rise for three or more decades. Using the World Health Organization classification, two types of t-MDS/AML are recognized, related closely to the therapeutic exposure: alkylating agent/radiation and topoisomerase II inhibitor.[147] The alkylating agent-related t-MDS/AML typically develops 4 to 7 years after exposure. Cytopenias are common, and ~65% of the patients present with myelodysplasia; the remaining present with AML but carry myelodysplastic features. Abnormalities involving chromosomes 5 (−5/del[5q]) and 7 (−7/del[7q]) are frequent. AML secondary to topoisomerase II inhibitors presents as overt leukemia, without a preceding myelodysplastic phase. The latency is brief, ranging from 6 months to 5 years, and is associated with balanced translocations involving chromosome bands 11q23 or 21q22. Solid tumors are related to the RT used to treat the primary cancer, typically have a long latency, and the risk is high among those exposed to irradiation at a young age.

Adult-onset cancer survivors diagnosed before 2000 have a less than twofold increased risk of subsequent neoplasms when compared with the general population (in particular among those diagnosed with their primary cancer at age <50 years).[148] Among individuals diagnosed with a primary cancer between 1992 and 2008 in the US, 8% to 11% develop a subsequent neoplasm.[149,150] The risk is highest among those diagnosed with their primary cancer at age below 50 years.[150] Cancer types sharing common risk factors, such as smoking or alcohol consumption (e.g., oropharynx, larynx, and lung), are the most common subsequent neoplasms. Over 50% of the patients with a subsequent neoplasm die of their second cancer.

The risk of subsequent neoplasms among childhood cancer survivors has been studied extensively. Childhood cancer survivors are at a 3-fold to 12-fold higher risk of subsequent neoplasms when compared with the general population.[151–156] Breast cancer is the most common subsequent neoplasm.[151] The risk of subsequent neoplasms remains elevated for more than 20 years from diagnosis of the primary cancer. Survivors are twice as likely as the general population to receive a diagnosis of subsequent neoplasm after age 40 years. The risk is increased for breast cancer, renal cancer, soft tissue sarcoma, and thyroid cancer in this age group.[157] Subsequent neoplasms are the leading cause of non-relapse late mortality.[158] Multiple subsequent neoplasms are common among aging survivors of childhood cancer. Cumulative incidence of a second subsequent neoplasm was reported as 47% at 20 years after the first subsequent neoplasm. A first subsequent neoplasm of a non-melanoma skin cancer identifies a population at high risk for a subsequent invasive neoplasm.[159]

Treatment with RT and specific chemotherapeutic agents are associated with a higher risk of subsequent neoplasms; female sex, older age at diagnosis, and earlier treatment era modify that association.[151] There is a dose-dependent increased risk for solid tumors after RT,[160] with the highest risks for tumors occurring in or near the treatment field. In addition to the well-known association with t-MDS/AML, alkylating agents and anthracycline chemotherapies also increase the risk of solid tumors.[161] Alkylating agents are associated with an increased risk for GI, thyroid, lung, breast, and bladder cancer, as well as sarcoma. Anthracyclines are associated with an increased risk for breast cancer. An evaluation of the association between temporal treatment dosing changes and subsequent neoplasm risk among childhood cancer survivors reveals that the risk of subsequent neoplasms at 15 years after initial cancer diagnosis remains increased for those diagnosed in the 1990s, although the risk is lower compared with those diagnosed in the 1970s. This lower risk of subsequent neoplasms is associated with reduction in therapeutic radiation dose.[162]

BMT performed across the age spectrum is associated with a 1.7-fold higher risk of subsequent neoplasms when compared with the general population.[163] The most common subsequent neoplasms include head and neck cancers, melanoma, non-melanoma skin cancers (both basal cell and squamous cell), bone tumors, breast and thyroid cancer, and lung cancer. Several host and clinical factors are associated with an increased risk for subsequent neoplasms after BMT, such as age at BMT, pre-BMT exposure to chemotherapy and radiation, exposure to TBI as part of conditioning, infection with oncogenic viruses (Epstein-Barr virus and hepatitis B and C viruses), and chronic GVHD.

Subsequent Malignancies Among Survivors of Acute Lymphoblastic Leukemia

Evaluation of large cohorts of patients with childhood ALL treated on therapeutic trials has shown that the cumulative incidence of subsequent neoplasms approaches 4% at 15 years from diagnosis of ALL.[164–168] Radiation-related subsequent neoplasms observed in ALL survivors include high-grade gliomas (glioblastomas and malignant astrocytomas), peripheral neuroectodermal tumors, ependymomas and meningiomas, thyroid cancer, and non-melanoma skin cancers.[167–169] The cumulative incidence of t-MDS/AML after therapy for ALL is generally low (<2%), except among those patients treated with epipodophyllotoxin therapy, where a cumulative incidence of 3.8% at 6 years has been reported.[170,171]

Subsequent Malignancies in Hodgkin Lymphoma Survivors

Childhood HL survivors demonstrate the highest risk of subsequent neoplasms; the risk ranges from 8.7-fold[151] to 14-fold[172] higher than the general population. The cumulative incidence of subsequent neoplasms among HL survivors ranges from 8% at 20 years to 18% at 30 years.[170,173,174] With follow-up extending to 40 years from HL diagnosis, the cumulative incidence of any solid subsequent neoplasm exceeds 25%.[172] Extended follow-up of early cohorts finds an excess risk for lung and gastrointestinal cancers, breast cancer, thyroid cancer, and bone/soft tissue sarcomas.[175–180] Risk factors for breast cancer among females includes receipt of chest RT between ages 10 years and 16 years and males treated with chest RT at age below 10 years are at highest risk of developing lung cancer. HL survivors who were treated with abdominal/pelvic RT and high-dose alkylating agents are at highest risk of developing colorectal cancer and females exposed to neck RT at age below 10 years are at highest risk of thyroid cancer. Among HL survivors at highest risk, the cumulative incidence of breast, thyroid, colorectal, and lung cancer is 45%, 17%, 9%, and 4%, respectively by age 50 years.[172]

The risk of subsequent neoplasms in survivors of adult-onset HL ranges from 2.4-fold[181] to 4.6-fold[182] when compared to the general population. The risk remains elevated 35 years or more after treatment. The 30-year cumulative incidence of breast cancer in women diagnosed with HL at age below 35 years is 13.8%.[181] The risk of any subsequent neoplasms is 1.3-fold higher for HL survivors with a first-degree relative with cancer; the corresponding excess risk is 3.3-fold, 2.1-fold, and 1.8-fold for lung, colorectal, and breast cancers, respectively.[181] A cumulative procarbazine dose of 4.3 g or more per square meter of body-surface area is associated with a significantly lower risk of breast cancer but a higher risk of gastrointestinal cancer.[182]

Early studies of HL identified the increased risk for t-MDS/AML among patients treated with MOPP-based therapy, which included mechlorethamine and cyclophosphamide.[183,184] These alkylating agent-associated t-MDS/AMLs are characterized by the presence of chromosomal abnormalities involving chromosomes 5 and/or 7, and are often preceded by myelodysplasia; the risk extends for a period of 10 to 15 years after exposure.

Subsequent Malignancies in Multiple Myeloma Survivors

The overall risk of any subsequent neoplasm in patients with MM ranges from 0.98- to 1.26-fold when compared with the general population.[185,186] The risk for t-MDS/AML is higher than that for the solid tumors, although some solid tumors are observed at a higher risk than the general population; these include gastrointestinal cancers, kidney cancer, bladder cancer, and melanoma and non-melanoma skin cancers. Population-based studies inclusive of patients treated prior to the widespread use of immunomodulatory agents (IMiDs) and proteasome inhibitors (PIs) find a 6.5-fold to 11.5-fold higher risk for t-MDS/AML when compared with the general population.[187–193] Prolonged alkylator therapy and conditioning with melphalan are associated with an increased risk of t-MDS/AML. There is a reduction in the incidence of t-MDS/AML noted as the use of prolonged upfront alkylating agent declines. The outcome after a diagnosis of t-MDS/AML is dismal, with a median overall survival between 8 and 14 months.[194–196] A modest increase in risk of subsequent neoplasms is observed in patients treated with lenalidomide. The risk is predominantly observed in patients who were conditioned with melphalan for an autologous BMT.[197]

Subsequent Malignancies in Non-Hodgkin Lymphoma Survivors

Subsequent neoplasms have been increasingly reported in the post-rituximab era in patients diagnosed with diffuse large B-cell lymphoma. The risk of subsequent neoplasms of t-MDS/AML has nearly doubled in the post-rituximab era (8.7-fold vs. 4.4-fold). Second thyroid cancer risk has also increased (2.3-fold vs. 0.7-fold). However, these findings are based on registry data, and there is a lack of therapeutic data at the patient level.[198]

Subsequent Breast Cancer

The incidence of breast cancer among young women treated for childhood cancer with chest RT ranges from 5% to 14% by age 40 years.[175,178,199–201] The latency after chest RT ranges from 7 years to 10 years, and the risk of breast cancer increases in a linear fashion with radiation dose, with an estimated relative risk of 6.4 at a dose of 20 Gy and 11.8 at a dose of 40 Gy.[202,203] Moreover, 40% of identified cases develop contralateral disease. The highest risk group is survivors of childhood HL treated with high doses of RT to an extended mantle field.[175,204,205] However, HL survivors treated with contemporary therapy using reduced volumes and lower doses continue to demonstrate an increased risk.[204,206] Women treated for other childhood cancers with high-dose RT to breast tissue also have an elevated risk.[151,178,199,201] Further, women treated for childhood cancer with whole lung irradiation have a greater risk of breast cancer than previously recognized, demonstrating the importance of radiation volume.[207] Finally, there is an increased risk of breast cancer in childhood sarcoma or leukemia survivors not exposed to chest radiation; in these patients, alkylators and anthracyclines are associated with increased risk of breast cancer.[208] A combination of radiation and anthracyclines may further increase breast cancer risk.[177]

The 25-year cumulative incidence of breast cancer is 11% after allogeneic BMT.[209] Allogeneic BMT survivors are at a 2.2-fold increased risk for developing breast cancer when compared with age and sex-matched general population. The median latency from BMT to diagnosis of breast cancer is 12.5 years. The incidence is higher among those exposed to TBI (17%) than among those who did not receive TBI (3%). The risk is higher among those exposed to TBI at a younger age.

There appears to be a protective effect of early menopause either because of alkylating agents or radiation dose above 5 Gy to the ovaries, suggesting that ovarian hormones play an important role in promoting tumorigenesis once an initiating event has been produced by radiation.[203,210,211] Breast cancer risk is 2.9-fold higher for survivors with $\geq$10 years of ovarian function after chest RT *vs.* less than 10 years and 1.8-fold higher for RT given within 1 year of menarche *vs* greater than 1 year from menarche. Risk decreases with decreasing age at menopause ($P_{trend} = 0.01$). Survivors with an age at menopause less than 20 years treated with hormone therapy had a lower breast cancer risk than premenopausal survivors. Over half (52%) of the radiation-related breast cancers are estrogen-receptor positive (ER^+); risk factors do not differ for ER^+ breast cancer. These findings suggest that endogenous hormones are key contributors to breast cancer observed among childhood cancer survivors. Hormone therapy given for premature ovarian insufficiency does not fully replace the function that endogenous hormones have in breast cancer development.[212]

Estimates of cumulative absolute risk for use in counseling patients have been developed.[205] For example, the cumulative absolute risks for an HL survivor who was treated at age 25 years with a chest radiation dose of 40 Gy or more without alkylating agents are estimated to be 1.4% after 10 years, 11% after 20 years, and 29% after 30 years.

Breast cancer-specific mortality at 5 years and 10 years is 12% and 19%, respectively.[207] Overall 10-year survival after breast cancer is 73%. Subsequent risk of all-cause mortality is 2.4-fold higher among childhood cancer survivors than among controls after adjusting for breast cancer treatment. While breast cancer-specific mortality is modestly elevated among childhood cancer survivors (HR, 1.3; 95% CI, 0.9 to 2.0), survivors are five times more likely to die as a result of other health-related causes, including other subsequent neoplasms and cardiovascular or pulmonary disease. The cumulative incidence of a second asynchronous breast cancer is also elevated significantly compared with controls ($P < .001$).[213]

Subsequent Thyroid Cancer

Thyroid cancer is observed after neck radiation for HL, ALL, and brain tumors, and after TBI for BMT,[151,164,167,170,214] and typically develops 10 years or more after RT exposure. The risk of thyroid cancer is 18-fold that of the general population.[215] RT at a young age is a major risk factor for the development of thyroid cancer. A linear dose-response relationship between thyroid cancer and radiation is observed up to 20 Gy, with a decline in the risk at higher doses, demonstrating evidence for a cell kill effect.[216,217] Female sex, younger age at RT exposure, and longer time since exposure are significant modifiers of the radiation-related risk of thyroid cancer.[218] Thyroid cancer develops after a latency of 8.5 years and is associated with an excellent outcome.

The risk of subsequent thyroid cancer is 1.2-fold to 3.5-fold higher among adult-onset cancer survivors when compared with the general population. The risk is highest after primary pancreatic cancer, soft tissue sarcoma, melanoma, chronic lymphocytic leukemia, diffuse large B-cell lymphoma, laryngeal cancer, kidney cancer, and central nervous system tumors.[219] However, use of registry data has precluded examination of association with treatment exposures or identification of high-risk groups.

Therapy-Related Myelodysplasia/Acute Myeloid Leukemia

Several studies have described an increased risk for t-MDS/AML after autologous BMT, particularly for HL or NHL. The cumulative probability of t-MDS/AML ranges from 1% at 30 months to 11.7% at 6 years after autologous BMT, with a median latency of 12 to 24 months after BMT (range: 4 months to 6 years).[220] The risk for t-MDS/AML usually does not extend beyond the first 10 to 15 years after therapeutic exposure. t-MDS/AML is the major cause of nonrelapse mortality in patients undergoing autologous BMT for HL or NHL.[221,222] t-MDS/AML after autologous BMT is the result of cumulative toxicity resulting from pre-transplantation therapeutic exposures (alkylating agents, topoisomerase II inhibitors, and radiation), stem cell mobilization and manipulation (exposure to etoposide for mobilization, and difficult stem cell harvests yielding smaller number of $CD34^+$ cells), conditioning with TBI, and multiple transplants.[221,223] The diagnosis of t-MDS/AML after autologous BMT confers a uniformly poor prognosis, with a median survival of 6 months in patients treated with conventional chemotherapy.

Therapy-related AML associated with topoisomerase II inhibitors is characterized typically by a shorter latency period (3 to 5 years from therapeutic exposure) than that seen for t-MDS/AML after alkylating agents, lack of a myelodysplastic phase, and the presence of 11q23 rearrangements with mutations in the mixed-lineage leukemia (*MLL*) gene. Epipodophyllotoxin-associated secondary AML depends more on the schedule of drug administration than total cumulative dose.[224]

Molecular Basis for Subsequent Neoplasms

Mutations in high-penetrance genes (e.g., Li-Fraumeni syndrome, *RB* [retinoblastoma], *NF1* [neurofibromatosis], *PTCH1* [Gorlin or nevoid basal cell carcinoma syndrome], *WT1* [Wilms' tumor] and *ATM* [ataxia telangiectasia]) could possibly modify the association between therapeutic exposures and subsequent neoplasms. Many genes associated with familial cancer syndromes are responsible for mediating cellular response to DNA damage (e.g., *ATM, BRCA*) induced by genotoxic insults such as radiation and chemotherapy. Cancer survivors who carry a deleterious high-penetrance mutation are likely to be at increased risk for subsequent neoplasms. However, the low frequency of these mutations in the general population suggests the attributable risk to the development of subsequent neoplasms is likely very small. The inter-individual variability in risk of subsequent neoplasms is more likely related to common polymorphisms in low-penetrance genes that regulate drug metabolism/disposition, or those responsible for DNA repair. Between 20% and 95% of the variability in cytotoxic drug disposition can possibly be explained by genetic variation,[225] and polymorphisms in genes involved in drug metabolism/disposition contribute to disease-free survival and drug toxicity.[226] Variation in DNA repair could possibly modify subsequent neoplasm risk among cancer patients exposed to DNA-damaging agents, such as radiation and chemotherapy. Finally, it is conceivable that gene-environment (therapeutic exposure) interactions could magnify functional impact of the polymorphisms.[227] There is some evidence that hematopoietic stem progenitor cells (HSPC) carrying age-related *TP53* mutations are resistant to chemotherapy and expand preferentially after treatment. The early acquisition of *TP53* mutations in the founding HSPC clone probably contributes to the frequent cytogenetic abnormalities and poor responses to chemotherapy that are typical of patients with t-AML/t-MDS.[228] Clonal hematopoiesis of indeterminate potential (CHIP) is an age-related condition characterized by somatic mutations in the blood of otherwise healthy adults. In patients undergoing autologous BMT for HL or NHL, CHIP at the time of transplantation is associated with increased risk of t-MDS/AML.[229]

Recommendations for screening and follow-up of survivors at risk for subsequent malignant neoplasms are reviewed in Table 101.1.[49,52,230,231]

Late Mortality

Late mortality has been described in detail for childhood cancer survivors and for survivors of adult-onset hematologic

il

malignancies treated with BMT. Childhood cancer survivors remain at risk for late mortality, and the excess mortality persists long after diagnosis.[158,232,233] All-cause mortality among survivors is eightfold that of the general population. Deaths are primarily due to recurrence/persistence of primary cancer or due to treatment-related complications, such as subsequent neoplasms, and cardiac or pulmonary causes. Extended follow-up of these cohorts demonstrates changing patterns of cancer-specific mortality with increasing time from diagnosis.[232,234] Thus excess risk for deaths from recurrence declines with time, while the excess risk for deaths from subsequent neoplasms and cardiovascular causes continues to increase; subsequent to 45 years from diagnosis, recurrence accounts for only 7% of the excess number of deaths while subsequent neoplasms and cardiovascular causes accounted for 51% and 26% of the excess number of deaths respectively (20628130). Childhood cancer survivors are at a 15-fold increased risk of subsequent neoplasm-related deaths, 9-fold increased risk of pulmonary deaths, and 7-fold increased risk of death due to cardiac causes when compared with the general population.[158] A recent study finds that the strategy of lowering therapeutic exposure over the past three decades has successfully translated to an observed decline in late mortality among 5-year survivors of childhood cancer.[235]

The high burden of morbidity carried by BMT recipients can result in late mortality. Mortality rates are fourfold to ninefold higher than in the expected population for at least 30 years after BMT, producing an estimated lower life expectancy of 30% compared with the general population, regardless of current age.[236] Relapse of primary disease is the main cause of death. Among BMT recipients, non-relapse-related mortality is greater among patients who are over 18 years of age when undergoing BMT, as well as among those with chronic GVHD. Compared with the general population, allogeneic BMT recipients are 3.6 times more likely to die of subsequent neoplasms, 15 times more likely to die of pulmonary complications, and 2 times more likely to die of a cardiac compromise. However, the conditional survival probability at 10 to 20 years after allogeneic BMT exceeds 80% for those individuals who were alive and disease free 2 to 5 years after BMT.[237,238] Autologous BMT recipients demonstrate a conditional 5-year survival that approaches 75% among those who have survived 2 years or more and approaches 90% among those who have survived 10 years after BMT. Among those who survive the first 10 years, non-relapse-related mortality exceeds relapse-related mortality.[239] (See box on Evaluating Survivors for Potential Late Effects.)

EVALUATING SURVIVORS FOR POTENTIAL LATE EFFECTS

To diminish the incidence and severity of untoward late effects and to improve the quality of survival for patients with hematopoietic malignancies, systematic evaluation of outcomes with subsequent modification of current and future therapies is required. To decrease late morbidity and mortality rates and to meet the specialized healthcare needs of this group of patients, ongoing comprehensive follow-up care with attention to early detection and intervention for late effects are essential.

Patients are generally eligible to enter formal long-term follow-up care when the risk for relapse of their primary disease is minimal. For most hematologic malignancies, this occurs when a patient is at least 2 years off therapy. When a patient enters long-term follow-up, the focus of care shifts from vigilant surveillance for disease recurrence to a survivorship model of health maintenance or promotion and management of treatment-related late effects. Effective management of these late effects requires ongoing surveillance, early intervention, and when possible, prevention.

The long-term complications of treatment for which an individual survivor is at risk are determined by several factors, including the patient's diagnosis, age at treatment, specific chemotherapeutic agents received (including cumulative doses), specific radiation fields and doses, therapy-related complications, degree of psychosocial support received, genetic predisposition, and current health-related behaviors (e.g., diet, physical activity, tobacco, and alcohol use).

POTENTIAL LATE EFFECTS BY DIAGNOSIS

Therapeutic approaches to hematologic malignancies vary widely depending on the patient's age at diagnosis, biologic subtype and staging of disease, year (era) of diagnosis, initial response to therapy, and physician/institutional preference. Even though two patients may share an identical diagnosis, their risks for late effects may differ significantly because of differences in therapy, age at exposure to therapy, or pharmacogenetics. General associations of late effects with conventional treatment for common hematologic malignancies are reviewed in Tables 101.2–101.4. The risk for specific late effects in survivors who have undergone HCT depends on the conditioning regimen, donor source, complications experienced during the transplantation process, presence or absence of GVHD, and prior cancer therapy. Transplantation-related sequelae have been reviewed throughout the text of this chapter.

Acute Lymphoblastic Leukemia

ALL is a heterogeneous disease. Therapy for ALL ranges from a relatively innocuous, antimetabolite-based approach for low-risk childhood ALL[240] to marrow-ablative therapy followed by HCT for very high-risk disease in all age groups.[241] The risk for long-term complications for individual survivors varies widely and is dependent on the specific therapy received as well as the patient's age at time of treatment.[242,243] Potential late effects that may occur as a consequence of conventional therapy for ALL are listed in Table 101.2.

TABLE 101.2 **Late Effects Associated With Conventional Therapy for Acute Lymphoblastic Leukemia and Non-Hodgkin Lymphoma**

Common Therapeutic Exposures	Potential Late Effects
Vincristine	Peripheral neuropathy, Raynaud phenomenon
Corticosteroids	Cataracts, osteopenia, osteoporosis, avascular necrosis
Asparaginase	No known late effects
Mercaptopurine	Hepatic dysfunction (rare)
Thioguanine	Portal hypertension, hepatotoxicity (when used continuously in maintenance therapy)
Methotrexate (systemic)	Osteopenia, osteoporosis, osteonecrosis, hepatic dysfunction (rare)
Methotrexate (intrathecal, high dose)	Neurocognitive deficits, clinical leukoencephalopathy
Cytarabine (high dose)	Neurocognitive deficits
Cranial or craniospinal irradiation	Neurocognitive deficits, clinical leukoencephalopathy, cataracts, hypothyroidism, second malignant neoplasm in radiation field (e.g., skin, thyroid, brain), short stature, scoliosis or kyphosis, obesity
Anthracyclines	Cardiomyopathy, arrhythmias, subclinical left ventricular dysfunction, secondary AML
Cyclophosphamide	Hypogonadism, hemorrhagic cystitis, dysfunctional voiding, bladder malignancy, secondary AML or MDS
Blood products	Chronic viral hepatitis, HIV

AML, Acute myeloid leukemia; *HIV*, human immunodeficiency virus; *MDS*, myelodysplastic syndrome.

Acute Myeloid Leukemia

Therapy for AML is generally more intense and of shorter duration than that used for treatment of ALL. Higher doses of anthracycline chemotherapy are often employed, as is consolidation therapy with HCT.[243] Typically patients with AML receive less CNS-directed therapy than those with ALL. Examples of potential late effects associated with conventional therapy for AML are listed in Table 101.3.

Hodgkin Lymphoma

Therapy for HL relies on the use of alkylating agents, antitumor antibiotics (including anthracyclines and bleomycin), corticosteroids, and RT. Some patients may be asplenic as a consequence of the staging procedures performed in the earlier era.[244] Examples of potential late effects associated with conventional therapy for HL are listed in Table 101.4.

TABLE 101.3 Late Effects Associated With Conventional Therapy for Acute Myeloid Leukemia

Common Therapeutic Exposures	Potential Late Effects
Anthracyclines	Cardiomyopathy, arrhythmias, subclinical left ventricular dysfunction, secondary acute myeloid leukemia
Corticosteroids	Cataracts, osteopenia, osteoporosis, avascular necrosis
Asparaginase	No known late effects
Cytarabine (high dose)	Neurocognitive deficits
Blood products	Chronic viral hepatitis, human immunodeficiency virus infection

TABLE 101.4 Late Effects Associated With Conventional Therapy for Hodgkin Lymphoma

Common Therapeutic Exposures	Potential Late Effects
Anthracyclines	Cardiomyopathy, arrhythmias, subclinical left ventricular dysfunction, secondary AML or MDS
Corticosteroids	Cataracts, osteopenia, osteoporosis, avascular necrosis
Bleomycin	Pulmonary dysfunction
Vincristine, vinblastine	Peripheral neuropathy, Raynaud phenomenon
Procarbazine, mechlorethamine, dacarbazine	Hypogonadism, infertility, secondary AML or MDS
Cyclophosphamide	Hypogonadism, infertility, hemorrhagic cystitis, dysfunctional voiding, bladder malignancy, secondary AML or MDS
Mantle irradiation	Hypothyroidism, premature cardiovascular disease, cardiac valvular disease, cardiomyopathy, arrhythmias, carotid artery disease, scoliosis or kyphosis, second malignant neoplasm in radiation field (e.g., thyroid, breast), pulmonary dysfunction
Inverted Y irradiation	Hypogonadism, infertility, adverse pregnancy outcome, second malignant neoplasm in radiation field (e.g., gastrointestinal)
Splenectomy	Acute life-threatening infections
Blood products	Chronic viral hepatitis, HIV

AML, Acute myeloid leukemia; *HIV*, human immunodeficiency virus; *MDS*, myelodysplastic syndrome.

Non-Hodgkin Lymphoma

The potential late effects after therapy for NHL are therapy specific and similar to those experienced by survivors of ALL (see Table 101.2).[244] Those patients whose treatment included HCT are also at risk for transplantation-related sequelae.

Chronic Myeloid Leukemia

Long-term survivors of CML have usually either undergone HCT or are receiving tyrosine kinase inhibitors long term. Among HCT recipients, there is a significant risk for late effects as a result of the transplantation-conditioning regimen, as well as treatment for and sequelae of GVHD.[245] With the transition in the early 2000s to tyrosine kinase inhibitor therapy for CML as the predominant treatment modality, the long-term effects of these agents are beginning to emerge in the growing cohort of CML survivors (see box on Late Effects Research: What Is Needed and the section Providing Clinical Care to Survivors).[246]

PROVIDING CLINICAL CARE TO SURVIVORS

A summary of cancer treatment and a survivorship care plan are critical components of care provision for survivors of hematologic

LATE EFFECTS RESEARCH: WHAT IS NEEDED

Medical Issues Faced by This Population

- Premature death.
- Second malignancies.
- Organ dysfunction (e.g., cardiac, pulmonary, gonadal).
- Impaired growth and development.
- Decreased fertility.
- Neurocognitive impairment.
- Difficulties obtaining employment and insurance.
- Overall reduced quality of life.

Issues to Be Considered by Physicians Providing Care to This Population

- Providing long-term follow-up care for cancer survivors.
- Models of care delivery.
- Guidelines for ongoing screening and management.

Major Clinical and Research Challenges

- Cancer survivorship research continually changing because of new:
- Therapeutic agents or combinations of agents (including targeted therapies).
- Radiation oncology techniques.
- Surgical procedures.
- Supportive care techniques.

Future Directions

Research is needed to:

- More clearly define survivors at greatest risk for specific outcomes.
- Identify genetic predispositions to certain key outcomes and the role of gene–environment interactions.
- Identify the role of lifestyle choices (e.g., alcohol, tobacco, diet, exercise) in modification of risks for late adverse outcomes.
- Understand the potential long-term impact of cancer therapy in order to effectively counsel survivors.
- Develop effective intervention strategies to prevent or minimize the impact of adverse late effects.
- Develop scientifically valid, evidence-based recommendations for clinical follow-up of survivors, which should include screening for potential late effects and application of proven approaches for health promotion.
- Much of the current information available relates to outcomes within the first decade after treatment, and only minimal data address the longer-term outcomes that may subsequently occur. Large sample sizes within the context of well-characterized cohorts with complete long-term follow-up remain the greatest challenge to sound survivorship research.

SURVIVORSHIP CARE PLANS

Survivorship care plans have been identified by the Institute of Medicine[248,249] as an important tool to facilitate follow-up care. Survivorship care plans should include both a summary of cancer treatment and a follow-up plan that can be used to enhance communication between care providers, coordinate care, and encourage health monitoring and promotion.[250,251] Specific elements of the survivorship care plan should include:

- Diagnosis, including histologic subtype and stage if relevant.
- Contact information for all cancer care providers and institutions where care was received.
- Surgical procedure(s) with dates.
- Chemo/biotherapy drugs received and completion dates for each.
- Radiation treatment dates with anatomical area(s) treated.
- Ongoing toxicities or treatment side effects.
- Genetic/hereditary risk factors or predisposing conditions, if relevant, including genetic testing results if performed.
- List of potential late and/or long-term effects.
- List of possible symptoms of cancer recurrence and surveillance testing schedule.
- Follow-up visit schedule, including who will provide care, and schedule of recommended screening/testing as indicated.
- Recommendations regarding general health maintenance/promotion.
- Information regarding common survivorship issues (e.g., emotional, financial, work/employment).

malignancies (see box on Survivorship Care Plans). Guidelines for long-term follow-up of survivors of hematologic malignancies and those who underwent HCT in childhood, adolescence, or young adulthood have been developed by the Children's Oncology Group[49] and are available at http://www.survivorshipguidelines.org; HCT long-term follow-up guidelines have also been developed by an international group of transplant experts.[52] In order to provide risk-based guideline-directed follow-up care, a comprehensive treatment summary is needed (Table 101.5) and a copy should be given to each survivor with instructions to share this information with all healthcare providers. Survivors should undergo annual comprehensive, multidisciplinary health evaluations with special attention to the detection of potential late effects specific to the patient's diagnosis and treatment history (see Table 101.1). Because certain late effects have prolonged asymptomatic intervals before becoming clinically evident (e.g., late-onset CHF as a result of anthracycline-induced cardiomyopathy), ongoing evaluation is important to identify and provide early intervention for these potential complications. Health education regarding potential health risks and risk-reduction measures should be provided to each survivor. Targeted health education materials related to potential late complications of therapy during childhood, adolescence, or young adulthood have been developed by the Children's Oncology Group[247] and are available at http://www.survivorshipguidelines.org. To optimize future follow-up care for all survivors, patients should be invited to participate in any relevant research studies for which they are eligible (see box on Late Effects Research: What Is Needed).

FUTURE DIRECTIONS

Cancer outcomes research enables researchers to study testable hypotheses and determine the effects of host- and therapy-related factors in the development of adverse outcomes ranging from carcinogenesis and organ dysfunction to psychosocial consequences. Opportunities also exist to explore gene and environment interactions that may modify susceptibility to develop adverse outcomes, thus providing insights into the identification of high-risk populations.

Better understanding of treatment-related toxicity has not only guided the design of less toxic therapies, but also the development of treatment summaries,[49] survivorship plans,[251] and efforts to harmonize survivorship guidelines worldwide.[252] It is important that

TABLE 101.5 Comprehensive Treatment Summary

Topic	Specific Information to Include
Demographics	Name
	Record number or patient identification number
	Date of birth
	Sex
	Race or ethnicity
Diagnosis	Date or age at diagnosis
	Referring physician or institution
	Treating physician or institution
	Presenting symptoms
	Past medical history
	Family history (including cancer in first- or second-degree relatives)
	Physical examination findings at presentation
	Initial diagnostics (complete blood cell count, chemistry panel, radiographic studies)
	Diagnostic procedures (biopsies, cytologic studies)
	Pathology (morphology, histology, cytochemistry, flow cytometry)
	Cytogenetics
	Central nervous system status (if applicable)
	Stage (if applicable)
	Metastatic sites (if applicable)
	Initial response to therapy (e.g., RER, SER, date first complete remission achieved)
	Relapse(s) dates, age at relapse(s), relapse site(s)
Treatment	Date of initial treatment (initiated and completed)
	Date(s) for treatment of relapse (initiated and completed)
	Final off-therapy date
	Chemotherapy agents received, including route of administration (list all)
	Cumulative doses (in mg/m^2) and age at treatment for all alkylators, anthracyclines, and heavy metals
	Dose ranges for cytarabine and methotrexate (e.g., standard dose vs. high dose $>1000\,mg/m^2$)
	Radiation fields, doses, shielding, age at treatment
	Surgical procedure(s)
	Transfusion(s), including all blood or serum products
	Stem cell transplantation(s), including donor source, preparative regimen, GVHD prophylaxis or treatment
	Other therapeutic modalities (e.g., immunotherapy, CAR-T)
Acute complications	Significant therapy-related complications (e.g., tumor lysis, septic shock, typhlitis, acute GVHD)
	Significant treatment required for complications (e.g., hemodialysis, amphotericin, aminoglycosides)
Complications after therapy	Significant complications after completion of therapy (e.g., herpes zoster, acute life-threatening infection after splenectomy)

CAR-T, Chimeric antigen receptor T-cell therapy; *GVHD*, graft-versus-host disease; *RER*, rapid early response; *SER*, slow early response.
Modified from Children's Oncology Group Summary of Cancer Treatment, 2018. http://www.survivorshipguidelines.org.

we continue to follow contemporary cohorts of cancer survivors to determine how therapy modifications affect the prevalence and spectrum of late effects. It is important to apply known interventions that can reduce the impact of cancer and treatment-related late effects on quality of life, morbidity, and mortality, as well as to develop and test new interventions. For example, survivors of HL treated with chest radiation have an increased risk of developing lung cancer, and tobacco use increases this risk 20-fold. Successful smoking prevention and cessation strategies among survivors can decrease the risk of this prevalent and highly morbid cancer of adulthood, while also decreasing the development and progression of atherosclerosis and other subsequent malignant neoplasms (SMNs). Screening of young women at increased risk of breast cancer due to chest radiation has already been mentioned. Given the role of endogenous estrogen in radiation-related breast cancer risk, it is important to study whether chemoprevention using anti-estrogen agents would reduce the risk of breast cancer. Survivors of childhood cancer, particularly those who received radiation to the hypothalamic–pituitary axis, are also at risk of obesity. Obesity can exacerbate the increased risks of CVD associated with anthracycline chemotherapy and RT to the chest. Modifiable CVRFs, such as hypertension, can potentiate the risk of major cardiac events and both behavioral and medical interventions can potentially reduce these risks. However, interventions need to be targeted to those at highest risk for developing these complications. There is therefore a need to develop risk prediction models that integrate the clinical/demographic profile of the patients with their genetic profile such as those developed to identify BMT survivors at risk for cognitive outcomes.[136]

The growing population of cancer survivors carries a significant burden of morbidity, necessitating comprehensive long-term follow-up of these survivors.[253] This follow-up should ideally begin at the completion of active therapy, with a documented summarization of therapeutic exposures and recommendations for follow-up, thus ensuring standardization of care received by the survivors.[248,249,251] However, many barriers prevent effective follow-up, the most fundamental being the lack of knowledge regarding survivorship issues demonstrated by both the long-term survivors and the primary care physicians caring for them. Shortcomings of the healthcare system also pose potential barriers and include logistical issues such as a lack of capacity within centers, training and educational deficiencies, inadequate communication between pediatric oncologists, and primary care physicians that subsequently provide the large bulk of follow-up.

Despite these unique opportunities, conduct of survivorship research faces several challenges. Cancer survivorship research is expected to evolve during the next several years as better treatment options, new agents, and combinations of agents are developed for the cancer patients who do not now survive. Targeted therapies (e.g., bispecific T-cell engager [BiTE] antibodies, chimeric antigen receptor T-cell therapy [CAR-T], gemtuzumab ozogamicin)[246] will contribute to increased survivorship. Evaluation of their late effects will need to keep in step with their increased usage. Refinements in RT and minimally invasive surgeries are intended to minimize late effects. Furthermore, the influence of genetic profiles on susceptibility to late effects, as well as their interaction with lifestyle exposures such as tobacco, alcohol, and diet, has not been fully explored. However, the multifactorial etiology of the adverse effects, coupled with the heterogeneous nature of the patient population, necessitates large sample sizes within the context of well-characterized cohorts with complete long-term follow-up, and this remains the greatest challenge to sound survivorship research.

PART IX TRANSPLANTATION AND OTHER CELL-BASED THERAPIES

CHAPTER 102

PRACTICAL ASPECTS OF HEMATOPOIETIC STEM CELL HARVESTING AND MOBILIZATION

Abba C. Zubair and Scott D. Rowley

Hematopoietic stem cell (HSC) products for autologous or allogeneic transplantation are available from bone marrow (BM), peripheral blood, or umbilical cord blood (UCB) sources. Bone marrow was the original source of cells for transplantation because of the ease and reliability of collecting adequate numbers of cells for transplantation, and it remains the standard with which other sources of HSCs are compared.

Peripheral blood stem cell (PBSC) products have virtually replaced bone marrow as the HSC component for autologous transplantation and are frequently used for allogeneic transplantation. The rapid engraftment kinetics of PBSCs compared with bone marrow is widely recognized. Median times to achieve an absolute neutrophil count greater than 500/μL and platelet transfusion independence after PBSC transplantation typically are approximately 11 to 14 days. The allogeneic donor has a wide range of options, including marrow, PBSC, or UCB products from human leukocyte antigen (HLA)-compatible or partially compatible related or unrelated donors. The availability of HLA-matched related or unrelated donors is the primary consideration in the selection of a donor, but donor health or donation preferences may restrict what products will be available to the recipient. The patient's physician may select a stem cell source based on the expected transplant outcomes. PBSC products, for example, have the greatest quantity of HSCs and will result in faster hematologic recovery compared with marrow or UCB transplants. Bone marrow transplantation has a higher risk of graft failure, resulting in a twofold higher probability of second harvest request compared with PBSC donation. In some reports, PBSC transplantation also results in a survival advantage. The transplant recipient may request a source of cells, but the donor has the right to decide about the method of donation. Although graft-versus-host disease (GVHD) prophylaxis with posttransplant methotrexate will slow engraftment, the kinetics of engraftment for the allogeneic PBSC recipient is similar to that experienced by the autologous PBSC recipient. A number of phase III studies involving either autologous or allogeneic HSC transplantation confirmed the more rapid engraftment kinetics for recipients of PBSCs,[1,2] and this effect is not limited to HSCs collected from the peripheral blood, because cytokine administration to the patient or donor before marrow harvesting will also increase the number of HSCs collected and result in quicker hematologic recovery. The disadvantages to using PBSC components compared with bone marrow or UCB for autologous or allogeneic transplantation include the possible need for multiple days of collection (especially for autologous transplantation), the inability to collect adequate components from all patients and donors, and a possibly higher risk for chronic GVHD or the occurrence of chronic GVHD that is more difficult to control (see box on Choice of Hematologic Stem Cell Product for Transplantation).

CHOICE OF HEMATOPOIETIC STEM CELL PRODUCT FOR TRANSPLANTATION

Virtually all patients undergoing autologous hematopoietic stem cell (HSC) transplantation will have peripheral blood stem cells (PBSCs) as the source of HSC, based on the following advantages: ease of collection, greater quantities of HSCs (resulting in faster hematologic recovery and shorter and less costly hospital stays), and potentially lower risks for tumor cell contamination of the graft.

The allogeneic donor has a wider range of options, including marrow, PBSCs, or umbilical cord blood (UCB) products from human leukocyte antigen-compatible or partially compatible related or unrelated donors. The transplant recipient may request a source of cells, but the donor has the right to decide about the method of donation. PBSC products have the greatest quantity of HSCs and will result in faster hematologic recovery compared with marrow or UCB transplants. In some reports, PBSC transplantation resulted in a survival advantage. However, PBSC transplantation is also associated with a higher risk for difficult-to-control chronic graft-versus-host disease (GVHD) and may not be appropriate for use in patients who would not benefit from a robust graft-versus-leukemia effect, such as those treated for nonmalignant disease. Infusion of two cord blood units may achieve a greater graft-versus-tumor effect (this concept has not been proven), even though one unit will be rejected. The much smaller quantity of HSCs in the cord blood product results in slower hematologic recovery, and the adult patient, in particular, may be at greater risk for post-transplant infection because of the relative immature immune system of the donor.

UCB from public banks has the advantage of being immediately available, reducing the time to transplantation. Targeting collection of UCB products from ethnic populations not well represented in donor registries will facilitate treatment of ethnic minority patients. The relative immunologic naïveté of the cord blood donor allows use of HLA-mismatched products without an undue increase in GVHD risk.[3] The much smaller quantity of HSCs in the cord blood product results in slower hematologic recovery and a higher risk for primary engraftment failure, which may be partially offset by infusion of multiple products; and the older adult patient, in particular, may also be at greater risk for posttransplant infections because of the relative immature immune system of the donor.

STEM CELL DONOR

Selection of Autologous Donor

The primary selection criterion for the patient undergoing autologous HSC collection and transplantation is the diagnosis of an illness amenable to treatment with a dose-intense regimen requiring HSC support. Extensive prior treatments, especially with marrow-toxic chemotherapy regimens or with radiotherapy, may prohibit collection of adequate quantities of autologous HSCs, which would exclude a patient from this treatment option. Proper management of patients with a disease amenable to dose-intensive therapy should include provisions for HSC collection before extensive marrow-toxic agents are administered. In general, however, any serious comorbid illnesses that would preclude either marrow or PBSC collection would also disqualify the patient from treatment with dose-intensive regimens used in preparation for autologous HSC transplantation.

Selection Allogeneic Donor

The selection of the allogeneic HSC donor is more complex. The HLA major histocompatibility complex is the primary consideration in selection of a donor for allogeneic HSC transplantation, since its loci contribute significantly to host-versus-graft (leading to immunologic rejection of donor HSCs) and to graft-versus-host (leading to GVHD and graft-versus-leukemia) reactions. Donor age, gender, and parity are secondary considerations in the selection of an allogeneic HSC donor. Mismatching for killer-cell immunoglobulin-like receptor ligands may reduce the risk for posttransplant relapse of disease. More than 30% of allogeneic HSC transplants from related or unrelated donors will involve ABO-disparate donors and recipients, and donor and recipient pairs may also differ for other red blood cell antigens, with no clear evidence of deleterious effect on engraftment, survival, or GVHD. Cancer, autoimmune disorders, and genetic diseases such as the hemoglobinopathies can be transmitted to the allograft recipient; thus, donor health is an important consideration in donor selection and determination of donor eligibility.

Evaluation of Hematopoietic Stem Cell Donor Suitability and Eligibility

The immediate pre-collection evaluation of a patient or donor is intended to address the risks of the collection procedure to the donor ("donor suitability") and the risks for transmission of disease from the donor to the recipient ("donor eligibility"). The same general health criteria apply to both bone marrow and PBSC donors. Patients undergoing autologous HSC collection and transplantation are not at risk for transmitting disease to themselves, and determination of donor eligibility is not medically required or economically justifiable, but these patients must be evaluated for their suitability for the collection procedures. All allogeneic and syngeneic HSC donors must be evaluated for donor eligibility, as well as suitability, using the same criteria currently applied to blood or other tissue donors, including a targeted history regarding behaviors exposing the donor to infection, recent or concurrent illnesses, and medication use. This evaluation of the allogeneic donor suitability and eligibility must be clearly documented in the donor medical record, with appropriate additional documentation of donor eligibility placed in the intended recipient's medical record before initiation of the transplant conditioning regimen. Older donors have a greater probability of comorbid medical conditions, which will increase the risks of the collection procedures, and the risks to the allogeneic donor with underlying health problems must be fully considered before subjecting the donor to HSC collection. Published standards describe evaluation of the donor for the risk of the donation process, as well as the risk for transmission of disease to the recipient.[4–6] Evaluation by appropriate consultants may be required before autologous or allogeneic donor approval is finalized. Procedures involving donors with acute infectious illnesses should be delayed, if at all possible, because of the risk for disease transmission. Genetic disorders, such as hemoglobinopathies, will be transmitted to the recipient as a direct consequence of stem cell engraftment. Cancer can be transmitted, as illustrated by the transmission of donor leukemia not detected during initial evaluation of the donor, and donors previously treated for cancer should be evaluated for the probability of recurrent disease that could be transferred to the immunocompromised recipient.

Collection of PBSCs is generally an outpatient procedure conducted in the clinic setting. In contrast, marrow harvesting has the luxury of the intensive support capability of the operating room. PBSC collection, therefore, should never be viewed as a safer alternative to marrow harvesting for the donor with underlying health problems. Pediatric donors present different challenges, based on the smaller size and varying ages (and ability to cooperate) of the donors (see box on Evaluation of the Allogeneic or Syngeneic Marrow or Peripheral Blood Stem Cell Donor).

EVALUATION OF THE ALLOGENEIC AND SYNGENEIC MARROW OR PERIPHERAL BLOOD STEM CELL DONOR

Hematopoietic stem cell (HSC) transplantation involves the infusion of a "blood product," and allogeneic and syngeneic donors must be evaluated for risks for disease transmission as per the current criteria for blood or tissue donation ("donor eligibility"). Exemptions from criteria that specifically address the risk for disease transmission are permissible, if the risks of excluding an otherwise appropriate donor outweigh the risks for disease transmission to the transplant recipient, who may not have an alternate donor. Informed consent must be obtained for the evaluation and collection procedures. Informed consent also must be specifically obtained for the release of protected donor health information to the transplant recipient, allowing proper informed consent for the transplant to be obtained. Minors and donors not competent to provide consent must be represented by a third party not involved in the care of the recipient. Ideally, similar courtesy will be provided to the adult competent donor.

Donors must also be evaluated for health issues that would increase the risks resulting from the collection procedures ("donor suitability"). For marrow donors, this includes the risks of anesthesia and harvesting in the prone position; for peripheral blood stem cell (PBSC) donors, evaluation should include the risks of mobilization medications and apheresis, including the need for venous catheter placement.

The donor collection facility's standard operating procedures for evaluation of HSC donors must meet the Foundation for the Accreditation of Cellular Therapy/Joint Accreditation Committee or AABB standards and United States Food and Drug Administration (or other equivalent regulatory agency) regulations, and include policies and procedures for the following:

- Education of donor, including education regarding procedures, risks and alternatives, and possible request for future donations;
- Medical history, including special attention to history of autoimmune disorders, arthritis, cardiac and vascular disease, and history of cancer;
- History of high-risk behaviors, such as recent tattoos, body piercing, sexual practices, and travel;
- Physical examination, including vein assessment (PBSC donors) and oral examination (marrow donors undergoing inhalational anesthesia);
- Laboratory studies, including verification of human leukocyte antigen typing, ABO typing, complete blood count, chemistry panel, infectious disease panel, urinalysis, ECG, CXR;
- Consent for the collection procedures and the release of protected health information to the stem cell recipient;
- Documentation of both donor eligibility and suitability before initiation PBSC mobilization and the transplant conditioning regimen.

Use of a donor who does not meet eligibility criteria and who poses a risk for transmission of disease requires appropriate informed consent both from the donor (for disclosure of this confidential health information to the recipient and for counseling of the recipient) and from the recipient (for use of the stem cell product). The potential conflict of interest between protecting donor confidentiality and patient needs must be recognized by the personnel caring for each person, and preferably, the donor and patient should be represented by different physicians.

Determination of Suitability for Peripheral Blood Stem Cell Donation

The PBSC donor is exposed to the risks of cytokine (and chemokine) administration and the risks related to the apheresis procedure, including the risks of central venous catheter insertion and use. No long-term health consequences have been associated with granulocyte colony-stimulating factor (G-CSF) administration, and the specific toxicities with these agents are described later. G-CSF may lead to a flare of autoimmune disorders and may increase the risk for blood clots, particularly for donors who are sedentary or who may be traveling shortly after the donation procedures.[7] The PBSC donor must be assessed for venous access before the patient receives conditioning, and consent for use of a central venous catheter must be obtained if the venous access is deemed inadequate for the apheresis procedure.

Determination of Suitability for Bone Marrow Donation

Anesthesia and blood loss present the greatest risks for serious complications to the bone marrow donor. Most marrow harvesting is performed under general anesthesia, which requires intubation for control of the airway for a surgical procedure being performed on a prone patient. Regional (spinal or epidural) anesthesia may not be effectively established, so patients and donors who express a preference for this form of anesthesia must be counseled about the potential need for general anesthesia. The health assessment must include questioning about a history of joint disease of the cervical spine and mandible, and examination of the mouth if general anesthesia requiring intubation is chosen. Patients and donors with comorbid conditions, such as aortic stenosis sensitive to changes in blood volume and blood pressure, may require anesthesia consultation and plans for invasive monitoring during the surgical procedure. A history of marrow fibrosis, pelvic irradiation, or pelvic tumor involvement may exclude a patient from marrow harvesting, although unilateral harvesting from the posterior and iliac crests and aspiration of the sternum may achieve adequate quantities of cells for transplantation.

Suitability and Eligibility for Umbilical Cord Blood Donation

Evaluation of the donor for UCB donation begins with a history of maternal and paternal illnesses and exposures to infectious diseases. Although linkage between the infant and the product is currently maintained, an update of infant health is not obtained at the time of transplantation, which may be several years after collection. Therefore, parental medical history includes specific questions addressing the risks for transmission of hereditary or acquired blood-borne diseases. A comprehensive genetic and family history should be obtained. Testing for infectious diseases is obtained from the mother at the time of collection to minimize loss of product through such testing.

Public UCB banks set criteria for the storage of units in order to avoid the collection and storage of UCB units that would not be acceptable for transplantation. Exclusion criteria for potential donors may include multiple gestation; premature delivery; active chorioamnionitis or sepsis; mother being the recipient of an organ transplant; mother with history of cancer; mother with high-risk behaviors or previously diagnosed with human immunodeficiency virus (HIV), hepatitis, or syphilis; and mother having an active venereal disease, such as vaginal herpes simplex and delivering vaginally.

There are also private cord blood banks that usually provide service to parents that enable collection, processing, and storage of cord blood units for future use by their children when they reach adult years. This is performed as an investment in the unknown potential for cord blood to be used to treat serious illnesses in the future. In general there is less than 1% chance of any child to receive HSC transplant in their lifetime, especially if the child has no family history of leukemia or lymphoma. Therefore, the general consensus is that routine cord blood storage in healthy babies is unnecessary because it is highly unlikely even if the child needs transplant in the future, the child's own cord blood will be suitable for the child's transplant due to possible risk for contamination with inherently cancerous cells. Also if the indication for the transplant is a genetic condition, the child's own cord blood will not be suitable because the cord blood will contain the same genetic problem.

In the absence of a suitable matched sibling or unrelated donor, finding a suitable UCB unit or haploidentical donor will be an important consideration. The choice between UCB and haploidentical transplant depends on the urgency of the transplantation, cell dose needed and the expertise at the transplant center. In terms of relapse rate, leukemia-free survival and transplant-related mortality, no significant difference was observed when UCB was compared with haploidentical transplant.

STEM CELL COLLECTION

Bone Marrow Collection Techniques

Bone marrow is typically harvested from the posterior iliac crests using virtually the same techniques used to obtain diagnostic samples in the clinic. The primary differences between obtaining diagnostic specimens and cell quantities adequate for transplantation are the volume of blood and marrow removed, which requires attention to fluid and blood component replacement during the procedure, and the need for appropriate anesthesia. Bone marrow harvesting from healthy donors presents little risk for serious morbidity, permitting the ethical recruitment of allogeneic and syngeneic donors, including pediatric bone marrow donors and donors not related to the recipient. Multiple aspirations are performed with collection of approximately 5 mL of marrow from each puncture site. If properly spaced, no more than two or three skin-puncture sites per side usually are required. Other harvest sites, such as the anterior iliac crests or sternum, can be used, but at increased risk for complications from accidental laceration or perforation of contiguous anatomic structures. For patients with a history of radiation or tumor involvement of one pelvic crest, adequate cells can be harvested from the anterior and posterior crests of the other side.

The prescription for marrow collection will define the desired quantity of nucleated cells per kg recipient weight to be collected. Ideally, this quantity of cells will be collected in a minimal total volume and procedure duration. Although transplant registries may require physicians to be experienced in marrow harvesting, defined as the number of procedures performed, few published studies report a correlation between such experience and harvest yields or donor complications.[8] The nucleated cell yield (cells per volume aspirated) appears greater for needles with side aspiration ports. Smaller quantities aspirated per "pull" also improves cell yield. Warming of the donor may improve cell yield. Quality-assurance management should review for each harvest team the nucleated cell yield per volume of marrow, total volume aspirated, use of blood replacement, and duration of anesthesia.

Marrow is collected in the day surgery suite using either general or regional anesthesia. With proper fluid and blood replacement, overnight hospitalization should not be required. Bone marrow harvesting necessitates placing the donor into the prone position, which has specific considerations to avoid complications directly resulting from this positioning. Donors must be supported, at a minimum, by positioning on chest rolls. For the healthy donor, the risks for serious complications from either general or regional anesthesia are minimal, although a multivariate analysis of adverse events performed by the National Marrow Donor Program for unrelated donors reported a higher risk for serious adverse events for donors receiving regional anesthesia.[9] Use of spinal or epidural anesthesia avoids the nausea that may occur with general anesthesia, especially for younger women, but hypotension from loss of vascular tone in the lower extremities often occurs as the volume of marrow is collected. General anesthesia is preferable for the donor with comorbid disorders, such as cardiovascular or cerebral vascular disease, because of the better control of donor airway and lower risk for hypotension during the harvest procedures. Local anesthesia is acceptable only if a very limited harvest is being performed, because local anesthesia does not achieve anesthesia of the marrow space and because large quantities of lidocaine, for example, are cardiotoxic.

Both heparin and acid-citrate-dextran-A (ACD-A) can be used for anticoagulation of bone marrow products. ACD-A decreases the accumulation of lactic acid and may be preferable, especially for products that will be transported or stored for longer periods before infusion or cryopreservation.[10]

Complications of Bone Marrow Collection

Anesthesia complications present the major health risk to the donor; marrow aspiration is generally well tolerated, although postharvest discomfort is experienced to some extent by all donors. Complications include hemorrhage and infections at skin-puncture sites. Severe hematomas and neuralgias rarely occur, and training regarding pelvic anatomy is required to decrease the risk for damage to vessels and nerves lying under or adjacent to the iliac crest harvest sites. Irritation of the sacral nerves may result from needle penetration through the pelvic bone or from blood tracking into the nerve roots, and requires several months of convalescence. Localized pain is common, may last for several days, and may require a brief period of opioid medication. In a survey of over 9000 donors for unrelated bone marrow transplantation, 82% reported collection site pain, with a median time to recovery of 3 weeks (see Figs. 102.1 and 102.2). Pain associated with the anesthesia procedures (throat pain, 33%; postanesthesia headache, 17%) was reported by a large proportion of the donors. Fatigue was reported by 59% of donors. Serious adverse effects were reported for 125 donors (1.35%), with 116 donors reporting serious complications considered to be a consequence of the collection procedures. Most of the serious complications ($n = 69$) were mechanical injury to tissue, bone, or nerve; and a smaller number ($n = 45$) were related to anesthesia. Infection and grand mal seizure were reported for one donor each. A retrospective survey of donor events reported by the European Group for Blood and Marrow Transplantation described almost 28,000 bone marrow donors, with one death from pulmonary embolism.[11] An additional 12 donors experienced severe adverse events, including four cardiac arrests (three during anesthesia), two episodes of severe hypertension, one pulmonary embolism from heparin-induced thrombocytopenia, one episode of pulmonary edema, one donor with a subdural hematoma, and three events not otherwise specified. This retrospective survey did not include all donors and may have underreported adverse events. This report, furthermore, did not report the experiences of related and unrelated donors separately. The adverse events reported by unrelated donor registries will underestimate the risks faced by donors for related recipients, who may undergo collection despite comorbid illnesses that would preclude participation in an unrelated donor registry. Most donors are able to return to routine activities 1 to 2 days after harvesting, The total recovery time for the 67 donors reporting serious mechanical injury was a median of 10 months (range: 1 to 96 months). Toxicity was

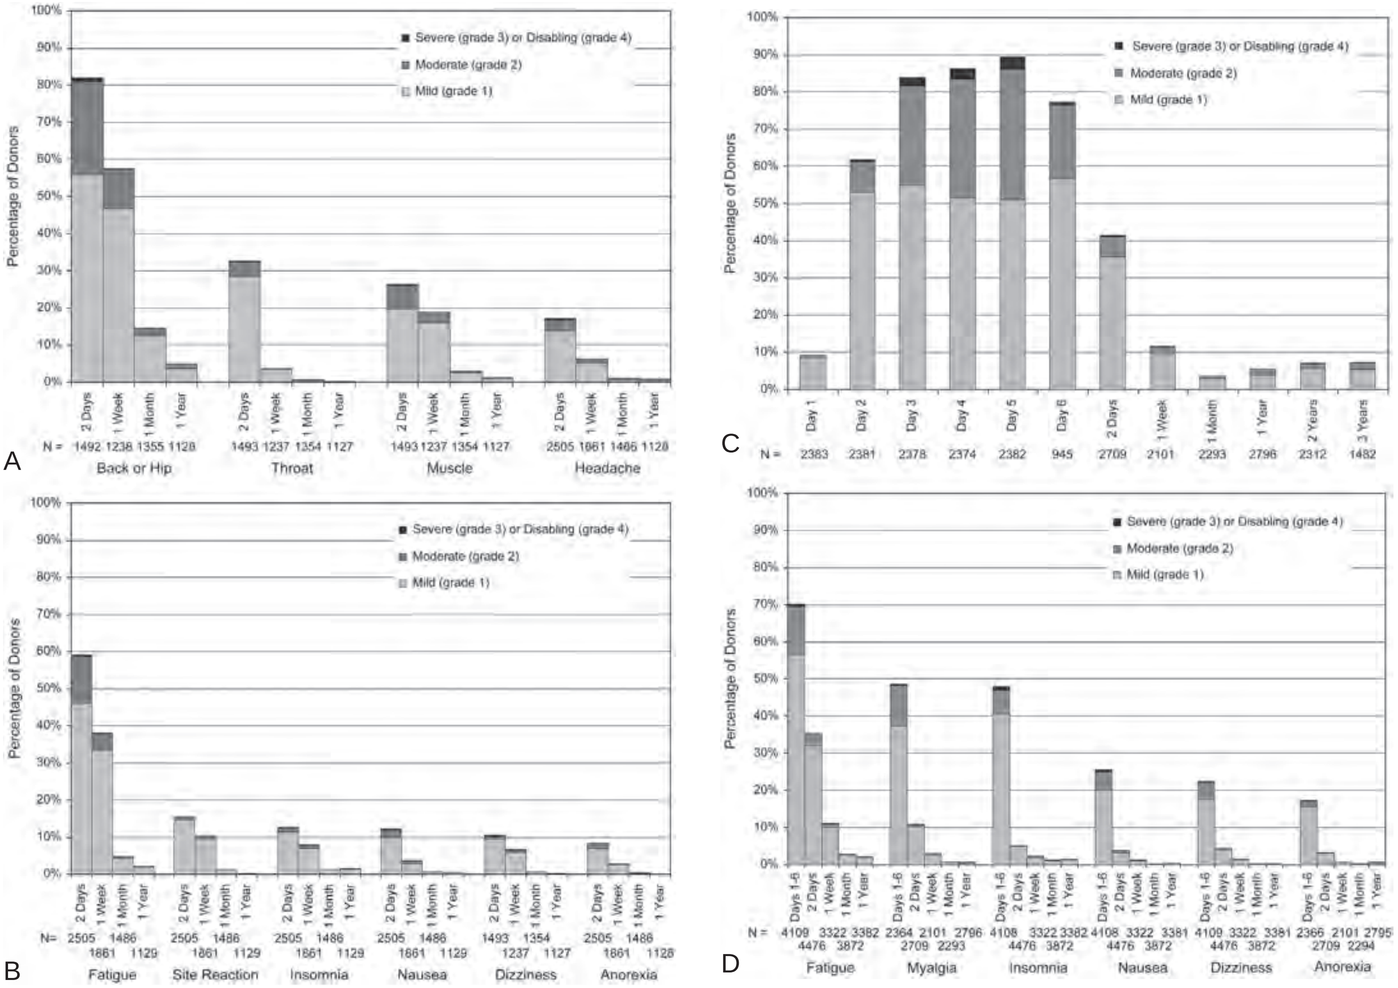

Figure 102.1 (A) Percentage of BM donors reporting pain at selected sites over time. Reports of pain and pain severity were collected at the indicated time points post-donation. Throat pain is largely restricted to donors receiving general anesthesia, whereas headache is more common in donors receiving epidural or spinal regional anesthesia. (B) Six most frequently reported body symptoms experienced by BM donors at the indicated time points post-donation. (C) Percentage of peripheral blood stem cell (PBSC) donors reporting bone pain over time. Reports of bone pain and severity of pain were collected at the indicated time points during mobilization, collection, and post-donation. Day 1 is the first day of filgrastim administration; day 5 is the first day of apheresis. Bone pain represents pain in at least one of the following sites: general bone pain, back, head, limb, joint, hip, and neck. The severity of bone pain is defined as the maximum grade among these pain sites. (D) Six most frequently reported body symptoms experienced by PBSC donors during mobilization and collection, and at the indicated time points post-donation. The percentages for day 1 to day 6 represent the frequencies of the highest grade of symptoms during mobilization and collection. *(From Miller JP, Perry EH, Price TH, et al. Recovery and safety profiles of marrow and PBSC donors: experience of the National Marrow Donor Program. Biol Blood Marrow Transplant. 2008; 14(9 Suppl):29–36. doi: 10.1016/j.bbmt.2008.05.018.)*

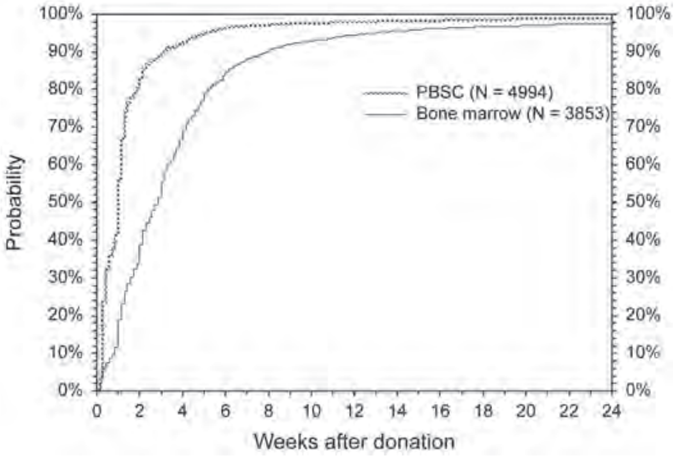

Figure 102.2 Kaplan–Meier plots of time to recovery from stem cell donation (first donations performed from November 2001 through March 2006). *(From Miller JP, Perry EH, Price TH, et al. Recovery and safety profiles of marrow and PBSC donors: experience of the National Marrow Donor Program. Biol Blood Marrow Transplant. 2008;14[9 Suppl]:29–36. doi: 10.1016/j.bbmt.2008.05.018.)*

more likely to occur for less experienced harvest teams, and harvest teams must address training and maintenance of harvest skills in their quality-assurance plans. Any team associated with a second severe mechanical injury should specifically be evaluated, in light of the very low probability of these events.

The usual volume harvested from healthy donors is approximately 10 to 15 mL of marrow per kilogram of recipient bodyweight to achieve the desired nucleated cell and CD34$^+$ cell doses. This results in a blood loss of 800 to 1000 mL for donors providing marrow for an average-sized adult recipient. The quantity of marrow harvested from autologous patients may be greater, reflecting previous chemotherapy given to these patients causing decreased marrow cellularity. Donors for pediatric recipients will lose proportionately less blood. Most patients and donors receive blood transfusions to alleviate symptoms of volume depletion. With proper pre-harvest autologous blood storage, use of homologous blood for healthy first-time allogeneic donors should be extremely rare. For a blood loss of less than 10 mL/kg of donor weight, salt solutions are acceptable for volume replacement. Colloid solutions, such as hydroxyethyl starch, can be used to avoid homologous blood transfusion for blood losses between 10 and 20 mL/kg donor weight. Blood transfusion will be required for larger blood losses (>20 mL/kg) or for patients with comorbid illnesses. Homologous blood transfusions must be irradiated to prevent transfusion-associated GVHD in the transplant recipient caused by “passenger lymphocytes” from the third-party blood donor. Donors undergoing a second harvest shortly after the first harvest are more likely to require homologous blood.[12] Oral iron supplements should be considered for healthy donors, particularly for female donors or donors from whom a proportionately large blood volume is to be harvested.

Collection of Umbilical Cord Blood Stem Cells

Advantages of this source of HSCs include the ability of public cord blood banks to target collections from ethnic-minority populations not well represented in the various unrelated donor registries and the relative immaturity of the donor immune system allowing transplantation of HLA-mismatched units without overwhelming GVHD. The primary obstacle to the widespread use of cord blood cells is the limited quantity of HSCs collected, and one public UCB bank predicted that from less than 5% to less than 38% (depending on the cell dose criterion for transplantation) of the units stored in that bank would be acceptable for transplantation of an 80-kg adult patient. The speed and success of engraftment are predicted by the total nucleated cell dose and, more important, by the quantity of CD34$^+$ cells or infused colony-forming units (CFUs).

CB Collection Techniques

UCB is collected from the placental vein after delivery of the infant and transection of the cord, either before delivery of the placenta by the obstetrician or by laboratory personnel after delivery of the placenta. Published reports conflict regarding the volume of UCB collected and the likelihood of obtaining a product inadequate for storage with either in utero or ex utero collection techniques. The timing of cord clamping after delivery of the infant is associated with the volume of cord blood collected, and greater volumes are collected with earlier clamping. Greater cell quantities were found for infants with greater birth weight, but no difference was found based on gender or gestational age. Ethnic background appears to predict the cell quantities, with smaller quantities of cells collected from persons from other ethnic populations compared with Whites. UCB is usually collected by cannulation of the umbilical cord veins with aspiration of the blood into a collection bag. Collection of cord blood into open containers results in an unacceptable rate of bacterial contamination. Perfusion of the placenta with salt solutions may increase the cell number collected, but this technique has not been widely adopted. Many cord blood banks reduce the volume of the product by red cell and plasma depletion to minimize storage space and to reduce possible infusion-related toxicities from mature blood cells contained in unfractionated cord blood units. Bacterial contamination of UCB products is of concern, especially in the collection of products for related donor transplantation by obstetricians with limited or no experience in HSC collection and processing. The identification and evaluation of the donor and the collection techniques used should be viewed as the first steps in a manufacturing process with adequately validated procedures, personnel training, quality control, and performance improvement oversight.

COLLECTION PERIPHERAL BLOOD STEM CELLS

The presence of HSCs in the peripheral circulation was suggested by animal studies as early as 1951.[13] Although the nature of the survival agent was not recognized at that time, parabiosis experiments demonstrated that some factor in the blood of a healthy animal was able to rescue another animal from the effects of lethal irradiation. Subsequently, a number of animal models demonstrated the presence of HSCs in the peripheral blood and the successful use of these cells to rescue animals from the marrow-lethal effects of radiation. The concentration of HSCs in the peripheral blood is normally very low, requiring the processing of large quantities of blood to collect the quantity of HSCs equivalent to what could be collected in a bone marrow harvest. For this reason, PBSC transplantation was initially used by a few transplant programs that explored this source of HSCs for patients who otherwise were ineligible for marrow harvesting, collecting cells during steady-state hematopoiesis or during the transient increase in circulating HSCs that occurred during recovery from marrow hypoplasia-producing chemotherapy. These early reports noted that engraftment could be achieved sooner after infusion of PBSC components compared with marrow cell transplantation. However, because of the occasionally limited quantity of HSCs that was collected from the peripheral blood, the kinetics of engraftment for some patients was considerably slower. The effective mobilization of HSCs achieved by cytokine or chemokine administration, and the reliability of same-day flow cytometric analysis in assessing the quality of the collection, are the direct bases for the rapid and widespread adoption of PBSCs as a source of HSCs for transplantation (see box on Mobilization and Collection of Peripheral Blood Stem Cell for Autologous Transplantation).

Mobilization

The self-renewal and differentiation of HSCs is controlled by the surrounding microenvironment of the stem cell niche(s) in which the HSCs reside. These niches are composed of a complex three-dimensional architecture of a variety of cell types, including sinusoidal

MOBILIZATION AND COLLECTION OF PERIPHERAL BLOOD STEM CELL FOR AUTOLOGOUS TRANSPLANTATION

Five important considerations when prescribing a mobilization regimen for collection of peripheral blood stem cells (PBSCs) for autologous transplantation are as follows: (1) A regimen of chemotherapy followed by granulocyte colony-stimulating factor (G-CSF) results in higher numbers of circulating $CD34^+$ cells than will be achieved with G-CSF alone. (2) The choice of chemotherapy (or cytokine alone mobilization) should be appropriate to the disease and stage of disease for the patient. (3) Each cycle of prior chemotherapy and any previous treatment with radiotherapy will decrease the response to mobilization therapy. (4) Tumor infiltration of the marrow will increase the probability of circulating tumor cells and will decrease the response to mobilization therapy. (5) Some patients will benefit from tandem cycles of dose-intense therapy, and the prescription should target adequate quantities of $CD34^+$ cells for these patients. With these considerations in mind, elective collection of PBSCs either before extensive treatment or after a limited number of cycles of debulking chemotherapy should be considered. Additional cycles of chemotherapy can be given after PBSC collection is completed, for those patients who require further tumor reduction before proceeding to transplantation. The timing of apheresis after chemotherapy and G-CSF mobilization is best guided by measurement of the level of peripheral blood $CD34^+$ cells. Daily or every-other-day quantification of these cells can be initiated after the white blood cell count reaches 1000/μL. Patients with poor mobilization of $CD34^+$ cells should be considered for addition of a chemokine such as plerixafor to improve $CD34^+$ cell yield and reduce the costs associated with daily doses of G-CSF, laboratory testing, apheresis procedures, and cryopreservation. Patients who fail to mobilize may have successful collections if given a short drug "holiday" before undergoing mobilization with high-dose G-CSF with plerixafor.

endothelial cells, sympathetic nerve fibers, cells of the osteoblastic lineage, macrophages, and mesenchymal stem cells that are responsible for controlling the balance between HSC quiescence, self-renewal, and differentiation. A number of pathways with mutually recognized cellular adhesion molecules and their respective ligands responsible for the spontaneous migration of HSCs from the stem cell niche, as well as the multistep process of homing back into the niche, have been identified. The mechanisms by which G-CSF and other cytokines promote mobilization of HSCs are being elucidated and appear to be an indirect effect (HSCs do not express receptors for G-CSF) on the CXC-chemokine receptor 4 (CXCR4)/stromal cell-derived factor-1 (SDF-1) axis mediated by monocytes and the sympathetic nervous system. The mechanisms of mobilization by chemotherapy and CXCR4 antagonists such as plerixafor are also being determined, and the elucidation of the mechanisms of mobilization and homing may result in more effective harvesting and transplantation techniques.

Cytokine Mobilization

The ability of recombinant hematopoietic cytokines to increase the level of myeloid progenitor cells in the blood, as well as mature blood cells, was reported in 1988 by different groups for both G-CSF and granulocyte–macrophage colony-stimulating factor (GM-CSF).[14,15] Subsequently, a number of different investigators reported the collection of PBSCs from patients using a variety of mobilization regimens, including cytokines alone, cytokine combinations, and combinations of chemotherapy with cytokines. Various other recombinant human hematopoietic cytokines, including erythropoietin and fusion molecules, increase the quantity of $CD34^+$ cells in the peripheral blood but have not been developed for clinical transplantation.

Granulocyte Colony-Stimulating Factors Including Biosimilars

G-CSF is the cytokine most commonly used because of its efficacy compared with other cytokines and its relatively benign toxicity profile. Recombinant methionyl human G-CSF (filgrastim) and recombinant human G-CSF (lenograstim) were the two forms of this cytokine initially available for clinical use. There are slight differences between these two similar cytokines in their ability to mobilize PBSCs. Watts and colleagues[16] studied 20 healthy volunteers and found that peak levels of colony-forming unit–granulocyte-macrophages (CFU-GMs) in the peripheral blood were 28% higher after treatment with the glycosylated molecule (lenograstim), attributed to the higher specific activity of this form. De Arriba and colleagues[17] treated 30 women with breast cancer in a randomized study of these two drugs, using dosages containing bioequivalent units of activity and found no difference in mobilization of $CD34^+$ cells. The two forms have otherwise similar biologic activity and are not further distinguished in this discussion.

Regulatory agencies, including the United States Food and Drug Administration (FDA), the European Medicines Agency, and others, established regulatory pathways leading to approval of biologic medicines that are highly similar to an already-approved biologic product ("biosimilar"). In the United States, the Biologics Price Competition and Innovation Act of 2009 created an abbreviated licensure pathway for biological products shown to be "biosimilar" to or "interchangeable" with an FDA-licensed biologic product, known as the "reference product." This abbreviated licensure pathway permits reliance on existing scientific knowledge about the safety and effectiveness of the reference product, and enables a biosimilar biologic product to be licensed based on less than a full complement of product-specific preclinical and clinical data usually required before marketing a new drug. The biosimilar must show it has no clinically meaningful differences in terms of safety and effectiveness from the reference product. Only minor differences in clinically inactive components are allowable. Filgrastim-sndz is the first biosimilar drug approved by the FDA and is marketed with the same indication for use as filgrastim. Tbo-filgrastim, however, was licensed under a different mechanism, and does not have FDA approval for use in PBPC collection. The use of a biosimilar G-CSF in mobilization of PBPCs must be extrapolated from laboratory data such as mobilization of $CD34^+$ cells, and it is conceivable, although considered very unlikely, that differences in the mobilization of stem and other cells, as well as in toxicity to the donor, may occur. Clinical experience describing similar mobilization results are now being reported for these drugs.[18]

Mobilization of Hematopoietic Stem Cells Using Granulocyte Colony-Stimulating Factor

G-CSF is the most potent cytokine currently available for mobilization of HSCs. In a randomized study of healthy volunteers comparing G-CSF, GM-CSF, and the combination of both, Lane and colleagues[3] reported an average 0.99% $CD34^+$ cells in the peripheral blood of healthy donors treated with 10 μg/kg/day of G-CSF compared with 0.25% for donors treated with the same dose of GM-CSF. The quantity of $CD34^+$ cells in the peripheral blood before treatment averaged 1.6/μL. After GM-CSF treatment, the level increased to 3/μL, but with G-CSF, the level increased to 61/μL. Each group underwent one leukapheresis on the fifth day of treatment, and the collections from donors treated with G-CSF averaged 119×10^6 $CD34^+$ cells compared with 12.6×10^6 for the donors treated with GM-CSF.

The appearance of $CD34^+$ cells during administration of G-CSF follows a distinct time course, with the maximal level of $CD34^+$ cells occurring on day 5 after daily G-CSF administration. Smaller numbers of $CD34^+$ are present on days 4 and 6, and the level falls rapidly on subsequent days despite a continual rise in white blood cell (WBC) count.

The number of $CD34^+$ cells collected after G-CSF treatment is proportional to the number of these cells in the peripheral blood before initiation of the cytokine. Although doses as low as 5 mcg/kg/day have been used, there is a dose response to G-CSF, with higher average levels of $CD34^+$ cells achieved with 10 mcg/kg/day compared with 5 mcg/kg/day. With appropriate dosing of allogeneic donors, adequate numbers of $CD34^+$ cells can be collected in one procedure for transplantation of most patients. A similar dose response is observed in autologous patients and may extend to doses as high as 40 mcg/kg/day. An advantage to twice-daily dosing of G-CSF has been suggested but not confirmed. Anderlini and colleagues[19] compared administration of 6 mcg/kg given twice daily with 12 mcg/kg given once daily and found no differences in CD34$^+$ cells per liter of blood processed during the apheresis procedure or the total yield of CD34$^+$ cells per kilogram collected. In contrast, a second trial enrolling primarily pediatric patients noted better results with the twice-daily schedule.[20] Patients, especially those previously treated with chemotherapy or radiotherapy, will generally have lower quantities of CD34$^+$ cells mobilized.

Toxicity and Complications of Granulocyte Colony-Stimulating Factor

The toxicity of G-CSF has been most clearly defined in studies of allogeneic donors. The autologous patient will experience a similar toxicity profile, but with the added complications of the underlying malignancy and its treatment.

Almost all recipients of G-CSF will develop somatic complaints, of which skeletal pain is most prominent (see Fig. 102.1), but also fatigue, insomnia, and nausea. The somatic complaints are generally tolerable, and few donors will require reduction in dose or discontinuation of the medicine. At present, there appear to be minimal, if any, long-term health risks for the donor. Few serious complications of the mobilization regimen and donation process have been reported. G-CSF increases spleen size, with a rare patient or donor experiencing splenic rupture. G-CSF may induce a hypercoagulable state, which is of concern for donors (and patients) requiring central venous catheter placement or for those who may have other risk factors for the development of deep venous thrombosis (such as air travel immediately after the collection procedures). Patients with autoimmune disorders may experience a flare-up of their disease during administration of G-CSF, and a variety of case reports of ophthalmologic and other adverse events have been reported for healthy donors or patients treated with G-CSF.

Of concern is the possibility that cytokine administration will increase the risk for marrow dysplasia or malignancy. Although this is a theoretical concern in that these cytokines are known to stimulate growth of leukemia cells, no clinical evidence from large registry reviews of healthy donor experiences indicates that these agents will induce abnormalities in the HSC.

G-CSF administration results in a number of changes in blood counts and chemistries in addition to the coagulation factor changes. Alanine aminotransferase, lactate dehydrogenase, and alkaline phosphatase levels increase, and the levels of blood urea nitrogen and bilirubin may decrease. The elevation in alkaline phosphatase level is primarily of bone origin; γ-glutamyl transferase levels remain normal. These abnormalities of serum chemistries resolve within 2 weeks after discontinuation of the medication. G-CSF administration also will result in a decrease in platelet count, especially if the cytokine is administered over 5 to 10 days. WBC counts fall rapidly after discontinuation of G-CSF. In approximately 10% of donors, the WBC count may fall to abnormal levels (but generally still remain above 1000/μL), reaching a nadir 10 to 14 days after discontinuation of the cytokine before stabilizing at normal levels.

Plerixafor

Chemokines (chemoattractant cytokines) are a family of approximately 40 related, small proteins that influence leukocyte (and malignant cell) migration and function. Chemokines with varying effects on different WBC populations have been identified, as have a number of chemokine receptors. The roles of chemokines and chemokine receptors in the trafficking of HSCs into and from the bone marrow compartment are under active investigation.

In a preclinical study, administration to both mice and rhesus monkeys of a modified CXC chemokine growth-related oncogene-β after 4 days of G-CSF resulted in a fivefold increase in the number of circulating stem and progenitor cells compared with G-CSF alone, also with a much shorter time course of release, measured in hours. Furthermore, more rapid recovery of hematopoietic function was observed for animals given similar quantities of cells collected after administration of the chemokine and cytokine combination. Interleukin (IL)-8, a related ligand for the CXCR2, mobilizes stem cells within 15 to 30 minutes of injection into mice, which appears to involve increased matrix metalloproteinase-9 activity detectable immediately before the appearance of HSCs in the peripheral circulation.[21] Murine studies demonstrate a mobilizing effect of the chemokine SDF-1 and its receptor CXCR4 that can be blocked by neutralizing antibodies. The bicyclam molecule plerixafor disrupts SDF-1/CXCR4 binding and has been shown to result in mobilization of HSC in murine, canine, and nonhuman transplant models.

Similar signaling pathways are used for mobilization and homing of normal and malignant hematopoietic cells. Although PBSC products collected after G-CSF mobilization generally contain fewer detectable tumor cells than does bone marrow harvested from the same patient, the effects of chemokine treatment on the degree of PBSC contamination and on disease relapse after autologous transplantation remain to be established. For example, acute myelogenous leukemia cells express CXCR4 in varying levels, and homing of primary human acute myeloid leukemia cells into nonobese diabetic/severe combined immunodeficiency mice is CXCR4 dependent, similar to normal human stem cells. Similar studies of chemokine control on tumor cell growth, migration, and metastasis are being reported from a number of laboratories. There are now reports of a possibly increased risk of posttransplant myelodysplasia or acute leukemia after transplantation using plerixafor-mobilized cells, although others have reported that poor mobilizers (who are more likely to receive this chemokine) have a higher risk of posttransplant myelodysplasia, complicating determination of causation of this complication of transplantation.

COMBINATION REGIMEN

Plerixafor Plus Granulocyte Colony-Stimulating Factor

Plerixafor (AMD3100) is a small-molecule inhibitor of CXCR4. Clinical studies of HSC mobilization using plerixafor with or without G-CSF priming are being reported in both healthy donors and patients undergoing autologous or allogeneic HSC transplantation. In a study involving normal volunteers, a single dose of plerixafor was equal in mobilization of CD34$^+$ cells to administration of a standard 5-day course of G-CSF.[22] However, a single dose of plerixafor given on day 5 of a daily course of G-CSF administration resulted in a further 3.8-fold increase in circulating CD34$^+$ cells (as well as B and T cells, which may be important in allogeneic transplantation). Randomized phase III studies conducted in patients undergoing autologous PBSC transplantation in the treatment of multiple myeloma or non-Hodgkin lymphoma demonstrated a clear increase in CD34$^+$ cells collected by the addition of plerixafor to filgrastim.[23,24] Plerixafor was also effective in remobilization attempts for patients who failed initial collection goals. Plerixafor clearance is proportional to the degree of renal function in patients with renal failure. Minor gastrointestinal symptoms appear to be the most common toxicities of this medication.

Chemotherapy Plus Cytokine Mobilization

The number of HSCs in the peripheral blood is moderately increased during the early hematologic recovery phase after marrow hypoplasia-producing chemotherapy. Chemotherapy plus cytokine generally mobilizes greater numbers of PBSCs than either agent alone. This finding was confirmed in a randomized study comparing cyclophosphamide followed by G-CSF versus G-CSF alone, in which higher numbers of CD34 cells were found for the patients treated with the chemotherapy-based regimen. However, no differences in the degree of tumor cell contamination of PBSC components, speed of hematological recovery after transplantation, or survival probability were found. A wide variety of different chemotherapy regimens has been used successfully for mobilization of HSCs into the blood, with cyclophosphamide- or ifosfamide-based regimens most commonly used. The primary consideration is that the choice of chemotherapy used for mobilization must also meet the treatment needs of the patient. Demirer and colleagues[25] studied the effect of different chemotherapy regimens for mobilization of HSCs for patients with breast cancer. Four regimens were used, all involving cyclophosphamide (CY), but including etoposide with or without cisplatin, or paclitaxel. All patients also received G-CSF. The median quantity of $CD34^+$ cells collected on the first day of apheresis after cyclophosphamide mobilization was 0.9×10^6 per kilogram of patient weight. The addition of etoposide and then of etoposide and cisplatin increased the first-day yield to 8.1×10^6 and 3.5×10^6 $CD34^+$ cells/kg, respectively, in separate cohorts of patients. The median number of $CD34^+$ cells harvested on the first day of apheresis after cyclophosphamide plus paclitaxel was 11.1×10^6/kg, and more than 50% of the women mobilized with this last regimen achieved the target dose of $CD34^+$ cells in one apheresis procedure. Of the 100 women studied, 94 achieved the target dose of greater than 5×10^6 $CD34^+$ cells/kg. Only four patients failed to reach a lower but acceptable dose of 2.5×10^6 $CD34^+$ cells/kg.

Granulocyte-Macrophage Colony-Stimulating Factor Plus Granulocyte Colony-Stimulating Factor

Much of the early experience with the use of hematopoietic cytokines for mobilization of HSCs involved GM-CSF and chemotherapy. GM-CSF is not as potent as G-CSF, although as with G-CSF, there is a dose response in mobilization of PBSCs with GM-CSF over a range from 0.3 to 30 mcg/kg/day, without a plateau. In this dose-ranging study, however, the average increase in CFU-GM in the blood at this highest dose level again was only 8.4-fold. In a randomized study comparing GM-CSF with G-CSF, or both drugs used in sequence after chemotherapy administration, patients had faster recovery of counts, required less supportive care including transfusions, and achieved greater collections of $CD34^+$ cells if given one of the G-CSF–containing regimens.

Administration of GM-CSF results in somatic complaints and hepatic function abnormalities similar to those reported after G-CSF administration. In addition, 44% to 80% of patients experience fever, sometimes after each dose, as well as generalized or local skin reactions. Doses greater than 20 mcg/kg/day are poorly tolerated because of fluid retention, pleural and pericardial inflammation, and venous thrombosis. A "first-dose reaction," characterized by hypoxia and hypotension occurring within 3 hours of administration, has been described for some recipients, especially after intravenous administration.

Other Hematopoietic Cytokines

Recognition of the mobilization potential of G-CSF led many investigators to study other hematopoietic cytokines, including erythropoietin, monocyte–colony-stimulating factor, IL-3, PIXY 321 (a fusion molecule), and stem cell factor (SCF) for their capacity to mobilize HSCS into the peripheral blood. Used as single agents, these cytokines resulted in only an approximately 5- to 10-fold increase in circulating CFU-GM or $CD34^+$ cells.

Strategies for the Patient Who Is Difficult to Mobilize

Most patients achieve the targeted dose of $CD34^+$ cells after processing 20 to 30 L of blood in one to three apheresis procedures. However, approximately 5% to as many as 30% of patients in various series have inadequate collections because only small numbers of HSCs are present in the peripheral blood despite the administration of hematopoietic cytokines. With wide use of plerixafor in combination with G-CSF, the rate of poor mobilization has significantly diminished to less than 5%. Of note, the number of days of apheresis also predicts the kinetics of neutrophil engraftment independent of the $CD34^+$ cell dose infused, indicating an undefined measurement of graft quality, probably a reflection of the various quantities of $CD34^+$ cell subsets and $CD34^-$ stem cells, as well as the characteristics of the stem cell niche. Patient-specific factors predictive of poor mobilization include older age, marrow disease, prior radiotherapy, and prior chemotherapy. Approximately 50% of patients who fail to achieve the targeted dose of $CD34^+$ cells will achieve this goal on a second attempt. High-dose (15 mg/kg twice daily) G-CSF after a 2- to 4-week drug holiday to allow marrow recovery is one strategy. Combination cytokine therapy is also of potential value in this situation, and the combination of SCF with G-CSF may be effective for patients who reside in countries where SCF is available. The addition of GM-CSF to G-CSF is not of proven value. The addition of plerixafor will often be effective when used in combination with G-CSF for collection of PBSCs from patients who failed a prior mobilization attempt. Treatment with the use of cyclophosphamide- or ifosfamide-based mobilizing chemotherapy plus a cytokine regimen also will be effective, but will be associated with increased toxicity. Bone marrow collection is very unlikely to achieve an acceptable product in that the poor mobilization of PBSCs predicts for a poor marrow harvest. Patients who fail initial collection attempts will frequently fail subsequent attempts, and transplantation of these patients with a lower dose of $CD34^+$ cells (as low as 1×10^6 $CD34^+$ cells/kg) may be an option.

It is, therefore, strongly preferable to avoid collection failure. Consideration should be given to the prophylactic collection of PBSCs early in the course of treatment for patients who later may be candidates for autologous HSC transplantation but who are advised to receive multiple courses of therapy or therapy involving alkylating agents or radiation therapy. HSCs can be collected and cryopreserved before extensive therapy while the patient has good marrow function and stored for years without obvious progressive loss of engraftment potential.

COLLECTION OF PERIPHERAL BLOOD STEM CELLS BY APHERESIS

Apheresis Technology

A number of apheresis devices are available for separating mononuclear cells (MNCs) containing HSCs from the peripheral blood. The devices may be classified as continuous flow (e.g., Fenwal CS3000, COBE Spectra, Spectra Optia [CMNC platform only], Fenwal Amicus) or discontinuous flow (e.g., Haemonetics family of equipment). Discontinuous-flow devices have the advantage of requiring only a single venous access. Continuous-flow devices require two access lines for aspiration and return of blood, but they process much larger volumes of blood in a shorter period of time. All apheresis devices collect MNCs. Continuous-flow devices are more efficient in the collection of PBSCs and are, accordingly, preferred over discontinuous-flow devices (see box on Physician Prescription for Apheresis and Peripheral Blood Stem Cell Processing). The ideal apheresis device will have: a high efficiency of $CD34^+$ cell collection with minimal contamination of the product by mature blood cells such as granulocytes, which complicate subsequent processing and can increase infusion toxicity; rapid blood processing with minimal anticoagulant use reducing toxicity to the donor; and minimal depletion of platelets. The various apheresis devices, in general, have

PHYSICIAN PRESCRIPTION FOR APHERESIS AND PERIPHERAL BLOOD STEM CELL PROCESSING

The attending physician should be aware of apheresis and laboratory procedures in order to maximize the value of peripheral blood stem cell (PBSC) products. The choices of venous access, anticoagulant(s), blood volume processed, target dose of CD34$^+$ cells, and cryopreservation volumes can be individualized. Apheresis unit staff may ask for guidance regarding pain medications, concurrent medications, and blood transfusions (although it is advisable to avoid transfusion during the apheresis procedure because of citrate or other reactions, and because changes in the hematocrit may affect the efficiency of the collection). Adequate numbers of CD34$^+$ cells can be collected for more than one cycle of chemotherapy. It is important to communicate with the cryopreservation facility if PBSC components will be used to support more than one cycle of chemotherapy or if dimethyl sulfoxide toxicity is of concern, in order to facilitate appropriate packaging of each product. Current cytometric techniques for quantification of CD34$^+$ cells require at least 1 h of processing, so it may not be practical to prescribe the number of CD34$^+$ cells to be frozen in each bag. However, it is possible to divide the component into the number of bags equaling the number of anticipated infusions so that equal numbers of CD34$^+$ cells will be available for each.

similar efficacies in collecting CD34$^+$ cells from the peripheral blood, but may vary in processing time, and in final product volume and mature blood cell contamination.

Apheresis technology is widely used for collection of platelets and other blood products from healthy donors and is considered to be without major risk to the donor. The important safety considerations for PBSC collection are the same as for platelet collection and include the venous access to be used for the procedure, the extracorporeal volume of blood during the procedure, and the solutions administered to the donor. Of note, however, PBSC collection for autologous transplantation involves patients with underlying medical conditions who may require considerable nursing care during the procedure. In a prospective evaluation of 2408 healthy unrelated volunteer donors, apheresis-associated adverse events were reported by 20% of female donors ($n = 964$) and 7% of male donors ($n = 1444$) on the first day of apheresis, falling to 10% and 4%, respectively, on the second day of collection (if performed). Most (51%) of reported adverse events were related to citrate infusion. A smaller proportion of donors (22%) reported problems with venous access. Rare (1% to 6% of events) adverse events included hypertension or hypotension, allergic reactions, fatigue, and syncope. The placement of a central venous catheter was required by 17% of female donors and 4% of male donors. Also, larger-volume and repetitive exchanges will result in platelet depletion. The platelet count may reach its nadir several days after completion of the apheresis collections and discontinuation of G-CSF, and donors should be counseled in this regard.

Important caveats are that the donors in this analysis from the unrelated donor registry met strictly defined health criteria and were between 18 and 69 years of age. A higher probability of adverse events may be expected in patients and in donors of older (or younger) age. For example, in an older retrospective publication, Goldberg and colleagues[12] studied the complications occurring during 554 PBSC collections from 75 consecutive patients. Patient diagnoses and the mobilization treatment regimens were varied. All but one patient had subclavian or jugular venous system catheters placed for apheresis. A median of nine collections per patient were performed using a discontinuous-flow apheresis device. The most common problems were related to the venous catheters: 50% of patients developed at least one occlusion. Hypocalcemia occurred in 14.6% of patients and hypotension in 13.3%. Sixteen percent of patients experienced infectious complications during the PBSC collection period.

Staffing of the apheresis unit should be appropriate for the medical condition of the patients undergoing apheresis. Staffing must include nurses familiar with the care of the oncologic patient who may be recovering from marrow hypoplasia complicated by neutropenic fever requiring multiple medications and the care of a central venous catheter. Collection of PBSCs by apheresis in the outpatient setting should be performed only after careful review of the medical support requirements for the individual patient or donor, and it should never be assumed to be a safer alternative for the donor or patient with a serious comorbid illness than marrow harvesting conducted in the intensive care setting of the operating room.

Timing of Apheresis Using Granulocyte Colony-Stimulating Factor and Chemotherapy

A major problem with chemotherapy-based mobilization regimens is the difficulty in determining the optimal time to commence HSC collection. Apheresis devices can collect only those CD34$^+$ cells actually being released into and circulating in the peripheral blood. It is possible to estimate the quantity of CD34$^+$ cells that will be collected during apheresis by multiplying the quantity of CD34$^+$ cells in the blood by the total volume of blood processed during the apheresis procedure and by the efficiency of the apheresis device in collecting these cells. If the device has an efficiency of 50% and the patient undergoes a 10-L exchange, approximately 5×10^7 CD34$^+$ cells will be collected for a peripheral blood level of 10 CD34$^+$ cells/μL and 5×10^8 CD34$^+$ cells for a blood level of CD34$^+$ cells that is 10-fold higher. Although many protocols call for initiation of apheresis after chemotherapy mobilization when the WBC count has recovered to greater than 1000/μL, there is a poor, if any, correlation between the peripheral blood white cell or MNC counts and the CD34$^+$ cells in the peripheral blood. Characteristics that suggest a higher CD34$^+$ cell level are a rapidly rising WBC count, shift in differential to immature myeloid cells, circulating nucleated red cells, and platelet transfusion independence. However, it is much more cost-effective to obtain an actual measurement of CD34$^+$ cells in the blood and to time the apheresis collection when these cells are present in adequate numbers. Fig. 102.3 shows such a relationship for patients with lower concentrations of CD34$^+$ cells in the peripheral blood and illustrates the very poor collections obtained when the peripheral blood CD34$^+$ count is less than 10/μL. Although there is considerable error in the enumeration of CD34$^+$ cells at levels less than 5/μL, this error is not clinically relevant because even a doubling of the CD34$^+$ cells in this low range still results in a very poor apheresis yield.

The level of CD34$^+$ cells in the peripheral blood at which to start apheresis is a clinical decision. Although levels in the range of 50 to 100/μL or greater will reduce the number of apheresis procedures necessary to achieve a target goal of CD34$^+$ cells, each day's delay in initiating apheresis incurs the costs of additional cytokine administration and blood testing. In some patients who previously

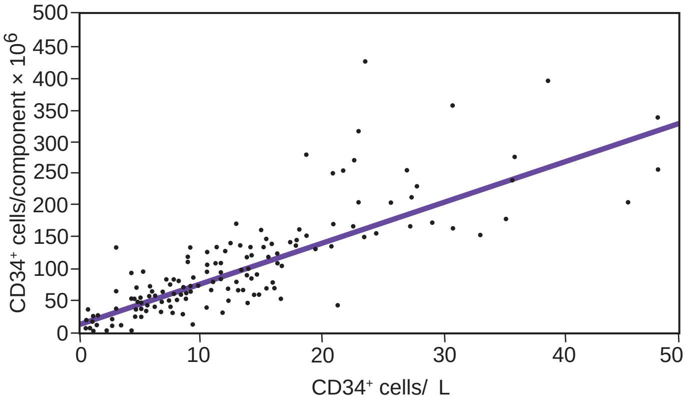

Figure 102.3 RELATIONSHIP BETWEEN QUANTITY OF CD34$^+$ CELLS IN THE PERIPHERAL BLOOD AND NUMBER COLLECTED BY APHERESIS USING APHERESIS AND FLOW CYTOMETRIC TECHNIQUES. Data shown are limited to peripheral blood CD34$^+$ cell numbers <50.0/μL ($n = 157$, $r = 0.82$, $P < .001$).

have undergone extensive treatment and who may show a slowly rising WBC count, multiple apheresis procedures may be necessary to achieve the target goal. No patient should undergo apheresis if the peripheral blood CD34$^+$ cell count is less than 5/μL (see Fig. 102.3). For patients with CD34$^+$ cell counts in the range of 10 to 20/μL, it is possible to process more blood per day using large-volume leukapheresis (LVL) techniques, thereby reducing the numbers of days the patients are required to return to the apheresis unit. Most patients mobilized with chemotherapy have a rising CD34$^+$ cell count in the peripheral blood, so starting apheresis the day after the patient has achieved a desirable CD34$^+$ level generally is feasible.

The timing of apheresis after G-CSF mobilization differs from the timing after chemotherapy and cytokine mobilization. For both patients and healthy donors, the peak concentration of CD34$^+$ cells occurs on day 5 of G-CSF administration (after four daily doses). Lower levels are present on day 4, and the concentration continues to fall after day 6, even if cytokine administration is continued and despite a possible continued rise in WBC count. Thus, PBSC collection should be initiated on day 4 or 5 of G-CSF administration. The kinetics of CD34$^+$ cells in the peripheral blood for patients and donors mobilized with G-CSF alone are so reliable that monitoring of peripheral blood levels is not necessary unless there is concern that the patient has failed to mobilize cells and it is practical to obtain the cell count rapidly enough to initiate apheresis on the same day.

Timing of Apheresis Using Granulocyte Colony-Stimulating Factor and Plerixafor

Plerixafor administration results in a rapid mobilization of HSCs into the peripheral blood, with peak CD34$^+$ cell and CFU-GM concentrations occurring about 6 to 10 hours but with a wide range of activity extending to over 24 hours after administration of a dose of 240 mcg/kg. The initial phase III studies demonstrating the efficacy of this agent in patients failing to mobilize adequate cells with G-CSF alone required administration of plerixafor about 10 hours before apheresis, and then daily administration of plerixafor on the same schedule until completion of collections. The broad duration of activity may allow alternate timing schedules and, conceivably, two apheresis procedures after one dose of plerixafor (particularly for patients with renal impairment). In a study of 11 patients who failed two previous attempts to collect PBSCs using G-CSF alone, Lefrère et al.[26] found an early rise in circulating CD34$^+$ cells, as early as 3 hours, with a fall in circulating CD34$^+$ cells occurring after 8 to 12 hours. Plerixafor allows for rapid mobilization of CD34$^+$ PBSC especially when used in combination with G-CSF. However, according to the manufacturer the peak CD34$^+$ PBSC in the blood is achieved in 10 to 11 hours and therefore leukapheresis is recommended when the peak is likely to be reached. This creates a logistical challenge because if the collection is to start during regular working hours, the Plerixafor needs to be given in the evening the day before. Even though about 10 hours is needed to reach the peak CD34$^+$ cell level in the blood, CD34$^+$ cell level begin to rise as early as 1 hour post-plerixafor administration. Same day plerixafor and leukapheresis had been explored with some success, though it took more days to achieve CD34$^+$ PBSC collection goals.

Large-Volume Leukapheresis

The apheresis device has a uniform and fairly reproducible efficiency of collection. Thus, for a consistent quantity of blood processed through the machine, the quantity of CD34$^+$ cells collected is directly related to the number present in the peripheral blood. Greater quantities of CD34$^+$ cells can be collected by increasing the number of these cells in the peripheral circulation or by increasing the volume of blood processed in each procedure (LVL). For patients with lower CD34$^+$ cell levels, multiple apheresis procedures will be required to achieve the target dose of CD34$^+$ cells needed for transplantation. An alternate approach is to process the same total quantity of blood but in fewer, longer procedures. LVL is not standardly defined, but in general usage it refers to processing of more than two or three times the patient's blood volume. Typically, the quantity of blood processed is six or more times the patient's blood volume, often 25 to 36 L of blood. The advantage of LVL is that it reduces the number of days of cytokine administration and apheresis, with associated reduced costs of laboratory processing and testing. The apheresis techniques are the same as those used for processing of smaller volumes of blood, although blood flow rates may be increased to reduce the time required. The risks of LVL are the increased time required and the higher risk for citrate (or other anticoagulant) toxicity. Patients will also incur a proportional drop in platelet counts and may become profoundly thrombocytopenic.

Most reports of LVL describe the collection of more CD34$^+$ cells than are calculated to be present in the peripheral blood at the initiation of the apheresis procedure. This results from the ongoing release of cells from the marrow replacing those cells removed by apheresis (or returning to the marrow space). Apheresis of CD34$^+$ cells is a three-compartment system consisting of the extracorporeal circuit of the apheresis device (including the collection bag), the peripheral blood, and the marrow. It is not obvious that the apheresis technique itself "mobilizes" CD34$^+$ cells. Apheresis-induced mobilization, if it occurs, may be related to a decrease in divalent cations resulting from the citrate anticoagulant, possibly affecting cell adhesion forces.

Studies at the Fred Hutchinson Cancer Research Center demonstrated a continuous release of CD34$^+$ cells from the marrow (and, presumably, return to the marrow space).[27] Patients having higher levels of CD34$^+$ cells in the peripheral blood appeared to have a greater number of these cells circulating between the marrow and peripheral blood compartments. In this model the apheresis device merely serves as a siphon, removing these cells from the blood as they are released from the marrow. If this description of CD34$^+$ cell kinetics is accurate, it may be possible to deplete these cells from the blood and marrow by prolonged processing, but probably only if limited numbers of them are present in the marrow compartment. Also, the model suggests that higher blood flow rates used to shorten the apheresis procedure may be counterproductive for patients with low CD34$^+$ cell levels in the blood because of the slower rate of release of CD34$^+$ cells in these patients.

Anticoagulation During Apheresis

Anticoagulants are added to the blood during apheresis to prevent clotting in the extracorporeal circuit and clumping of cells in the product. Citrate anticoagulants have a proven record of safety in the apheresis of healthy platelet donors. The major drawback is the risk for a symptomatic decrease in the level of ionized calcium ("citrate toxicity"), especially during processing of large volumes of blood. Citrate ions chelate calcium ions (and other divalent cations such as magnesium), making them unavailable for Ca^{2+}-dependent metabolic reactions. ACD-A contains 10.67 g of citrate per 500-mL volume in the form of trisodium citrate and citric acid. Citrate is diffused throughout the extravascular space, and this diffusion is the first defense against citrate toxicity. The body size and difference in muscle mass between men and women results in an increased risk for citrate toxicity for women in particular and smaller donors in general. Metabolism by liver, kidney, and muscle also reduces the concentration of citrate. Metabolism of citrate becomes an important clinical consideration during processing of larger blood volumes or at higher rates of blood flow. The initial signs of citrate toxicity include circumoral or acral paresthesias and may progress to nausea, vomiting, loss of consciousness, tetany, and seizures. Because pediatric patients may not be able to relate the initial symptoms of the condition, citrate toxicity should be considered as the cause of any change of behavior, such as crying, during the apheresis procedure. Citrate toxicity is prevented by limiting the quantity of citrate infused, either by decreasing the blood flow rate through the apheresis device or changing the blood-to-citrate ratio. The processing of blood from patients experiencing the initial symptoms of citrate toxicity should be temporarily halted until the symptoms abate, and then resumed at a slower rate. The benefit of oral calcium supplements for these patients is not proven and may cause abdominal discomfort. Heparin can be used as a replacement for some or all of the citrate, although additional citrate should be added to the component bag to prevent clumping of platelets. Some centers that use citrate anticoagulants also administer intermittent or continuous infusions of calcium gluconate during the procedure, especially if large volumes of blood are being processed. However, excessive calcium replacement can induce cardiac dysfunction.

Venous Access

Adequate venous access is required for optimal apheresis technique. Continuous-flow apheresis devices require two-lumen access with a stable blood flow capacity generally greater than 20 mL/min. Single-lumen access may be used with discontinuous-flow apheresis devices, although at a much slower rate of blood processing. The great majority (≈95%) of adult male allogeneic PBSC donors have adequate arm veins for the procedure to be conducted "vein to vein," with female donors more likely to require alternate venous access. Some donors, especially those with small veins and undergoing several daily procedures, may require placement of a temporary venous catheter. Venous access for the patient undergoing collection for autologous PBSC transplantation is much more heterogeneous. Vein-to-vein procedures can be performed, even on several consecutive days, with proper phlebotomy technique and post-collection care of the phlebotomy site. Most patients received previous chemotherapy or are proceeding directly to transplantation, conditions for which tunneled access is commonly placed. Ideally, this venous access should be appropriate both for the apheresis procedures and the subsequent transplant. Length, lumen size, and wall stiffness all affect the blood flow that can be achieved through a catheter. For this reason, the commonly used dual-lumen Hickman or Broviac catheters are usually unsuitable for apheresis, as are all subcutaneously placed ports. Most triple-lumen catheters are inadequate because of the small lumen size. If such access is already in place, consideration can be given to replacement with a shorter, stiffer tunneled catheter or to placement of a temporary percutaneous dialysis/apheresis catheter. The catheters designed for dialysis and apheresis have adequate wall thickness to prevent collapse during aspiration of blood, as well as a tip design that decreases local recirculation of blood and the resulting decrease in apheresis efficiency. Catheters of 10 F or larger size are appropriate for adult patients. Pediatric patients, whose blood flow rates are considerably slower, may use catheter sizes of 5 to 7 F.

Pediatric Donors and Patients

PBSCs can be collected from pediatric patients, including infants. The special challenges of the pediatric patient arise from the fixed extracorporeal blood volume of the apheresis device, the need for venous catheters for blood access, and the management of a patient who may be unwilling or unable to rest quietly for the period of apheresis. It is especially important in management of the pediatric patient that timing of apheresis be optimal to minimize the number of procedures required to achieve the desired quantity of PBSCs. Given these considerations, a number of centers have reported successful collection of PBSCs from pediatric patients and donors.

Almost all pediatric patients undergo insertion of a venous catheter adequate for the flow rates expected, although older patients (>12 years) may tolerate vein-to-vein procedures. The whole blood flow rate for the pediatric patient is much reduced compared with that of adult patients, and catheters as small as 5 F may be adequate.

Appropriate management of fluid balance during the apheresis procedure is critical for the smaller patient. The volume of red blood cells contained in the extracorporeal circuit of the continuous-flow apheresis device could represent 30% to 50% of the red cell mass of a pediatric donor. Although discontinuous-flow devices are appealing because of the feasibility of performing apheresis with a single-lumen venous access, they may result in even higher extracorporeal volumes and should be avoided in the smallest patients. The obvious solution to this problem is to prime the apheresis device with ABO-compatible, irradiated red blood cells (leukocyte-depleted and cytomegalovirus-negative blood is also desirable) when the blood in the extracorporeal circuit is expected to exceed 15% of the patient's blood volume. Packed red blood cell units can be diluted with saline or albumin (to reduce the loss of plasma protein that may occur). The red cells remaining in the extracorporeal circuit at the completion of the run need not be returned ("rinse-back"), although if performed slowly with monitoring of vital signs, rinse-back may actually increase the hematocrit after the procedure and otherwise reduce the need for red cell transfusions for these patients. For the intermediate-size pediatric patient (weight 25 to 50 kg), the apheresis device can be primed with a 5% albumin solution. This step will reduce the albumin loss that otherwise would occur. However, clotting proteins and other proteins not contained in this solution may decrease with repetitive apheresis.

The pediatric patient may not exhibit or relate the prodromal symptoms associated with citrate toxicity. Continuous calcium gluconate infusion can be incorporated into the procedure, or heparin can be added to the citrate anticoagulant solution or used as the sole anticoagulant. Sedation of the pediatric patient is usually not necessary and hinders the ability to recognize the symptoms of citrate toxicity. (Some patients may require antihistamine premedication if the apheresis device is primed with red blood cells.) Centers routinely performing pediatric PBSC collection should design an environment conducive to the management of pediatric patients and develop support procedures that recognize the unique physical and cognitive features of pediatric patients.

The range in blood volumes for pediatric donors of differing ages is greater than the range for adult donors. Therefore, most centers set a goal for volume processed based on the individual's blood volume instead of a set volume (e.g., two blood volumes vs. 6 L of blood) for all patients. The pediatric patient may undergo LVL to achieve the target goal of HSCs with fewer procedures. Blood flow rates for pediatric patients are slower than for adults to minimize the risk for citrate reaction. As with adults, the timing of apheresis can be optimized by monitoring the quantity of CD34$^+$ cells in the peripheral blood.

Complications of Apheresis Collection

Even though most of the complications that occur during leukapheresis procedure to collect PBSC are due to anticoagulant use and/or central line, there are complications that may arise during the procedure that are related to mechanical or technical problems, and problems related to extracorporeal volume. In addition, cytopenia related to cells and platelets depletion may lead to bleeding problems. The mechanical and technical problems that may occur during collection include obstruction or leakage in the sets and hemolysis resulting from kinking or poorly placed tubing. Even though most of the apheresis machines are designed to trap air pockets, air embolism may still occur. Volume shift occurs when blood is drawn to fill the extracorporeal circuit. This may lead to development of vaso-vagal reaction that is typically manifested by nausea, diaphoresis, bradycardia, and pallor. Also, hypovolemic reaction can occur as a result of the volume shift that is characterized by tachycardia, hypotension, syncope, and more rarely, seizure-like reaction. Management includes placing the donor in Trendelenburg position and intravenous hydration.

HEMATOPOIETIC STEM CELL PRODUCT QUALITY

Hematopoietic Stem Cell Product Composition

The composition of the graft depends on its source (BM, PBSC, or CB) and whether HSC mobilization was involved and the type of mobilizing agent(s) used. Even though CD34$^+$ cell content in the graft is most important factor in the product, other cell types play important roles. Specifically, T cell subsets play a major role in facilitating GVHD, graft versus leukemia, and HSC homing and engraftment. Compared to BM, PBSC has the most T cells that may constitute about 30% of all the total nucleated cell content in the graft. The composition of T cells in the BM is about 10% and for CBU is about 20%. Because the T cells in CBU tend to be more immature, the risk of GVHD development is lower than in both BM and PBSC transplants.

The use and nature of mobilizing agent affect BM and PBSC composition. The use of G-CSF as mobilizing agent significantly increases the content of $CD14^+$ monocytes and $CD3^+CD4^-CD8^-$ natural suppressor T cells in a graft. Addition of plerixafor to chemomobilization plus G-CSF further increases the proportion of primitive $CD34^+$ cell subsets, total T and NK cell content in the graft.

$CD34^+$ Cell Enumeration and Dose

Quantification of CD34 antigen-positive cells by flow cytometry has become the standard of care for management of the PBSC donor because it provides a rapid and clinically relevant assessment of HSC content in the peripheral blood or in the PBSC product. This antigen is found on HSCs (including a variety of subpopulations) and limited populations of other blood cells, and can be identified using a variety of commercially available antibodies. If antibodies directly conjugated with dyes are used, the technique requires only about 1 hour of preparation time. Cell viability using propidium iodide or 7-aminoactinomycin D exclusion can simultaneously be determined if the cells are analyzed while still fresh, or the cells can be fixed after staining for analysis at a later date. Other antibodies can be added for analysis of CD34 subsets if desired (and if the flow cytometer has proper detectors to detect the different emission wavelengths of the fluorochromes used). A strong correlation exists between the numbers of $CD34^+$ cells and CFU-GM in the sample, but with ratios of about 5:1 to 20:1. Thus, CD34 analysis will provide data similar to that obtainable with cell cultures, except that the latter demonstrates the functional viability of the progenitor cells. Mobilized PBPC products contain a heterogeneous mixture of cells including $CD34^+$ cells belonging to different cell subsets. Subset analysis of $CD34^+$ cells will provide additional information regarding early and sustained engraftment after autologous PBPC transplantation but does not appear to be clinically useful for the patient who easily meets the PBSC collection goal.

The major difficulty with analysis of $CD34^+$ cells is the low frequency of these cells. Clinical decisions to initiate apheresis are being made for $CD34^+$ cell levels as low as 10/μL. This may represent a cell frequency that is 0.01% or less of the nucleated cells in the specimen. This enumeration is possible because of multidimensional measurements obtained by flow cytometry. Most cytometers can measure at least five characteristics of each cell, including size, granularity, and the presence of up to three different fluorochromes. Thus, the cells of interest can be separated in five-dimensional space, achieving discrimination of cells as rare as 1:10,000. The difficulties arise from developing an adequate technique that makes optimal use of the cytometer to measure these rare cells. Sources of errors include: (1) sampling of the HSC product, (2) cell counting, (3) cytometer calibration and operation, (4) choice of antibody and fluorochrome, (5) lysis technique, and (6) gating strategy. Moreover, cytometry provides a proportion of cells that must be multiplied by the cell count to obtain an absolute number. The steps involved in preparing a specimen for cytometry may alter the proportion of cells in the sample, and this error will be translated into an error in the absolute number. Clinically, this imprecision may explain some of the range in engraftment kinetics observed for patients receiving low doses of $CD34^+$ cells.

Bone Marrow

Total nucleated cell count is normally used as a surrogate for the stem cell content of the marrow product because the definition of adequate HSC products predated the availability of flow cytometric analysis of HSC content, and nucleated cell counting is the only quality-control measure easily performed during the collection procedure. For autologous transplantation, cell doses of 1×10^8 nucleated cells/kg are adequate. Based on early reports that smaller quantities increased the risk for engraftment failure, most centers target 3×10^8 nucleated cells/kg of recipient weight for allogeneic transplantation. However, those early reports were of patients being treated for aplastic anemia, in which engraftment failure is a more common event. A review of unrelated donor transplantation found that recipients of higher marrow cell doses experienced faster neutrophil and platelet engraftment, as well as better leukemia-free survival.[28] Pretreatment of the marrow donor with either GM-CSF or G-CSF may increase the number of myeloid progenitor cells harvested and decrease the period of posttransplant aplasia to that achievable by PBSC transplantation. $CD34^+$ cell dose is now being correlated with transplant outcomes—with more rapid engraftment kinetics, possibly lower transplant-related mortality, and better overall survival, for example, in recipients of allogeneic bone marrow products containing higher quantities of $CD34^+$ cells. $CD34^+$ cell count is now a routine component of bone marrow product quality control.

Peripheral Blood Stem Cells

The quantity of $CD34^+$ cells in a PBSC component varies greatly and is dependent on the number in the peripheral blood at the time of apheresis, the volume of blood processed, and the efficiency of the apheresis device. Therefore, any definition of an adequate component cannot include a set number of $CD34^+$ cells to be contained in any single apheresis component. Instead, one or more components will be collected to meet the appropriate dose of these cells for transplantation. The dose of $CD34^+$ cells required for infusion depends on the intended treatment regimen. For marrow-ablative regimens, increasingly higher $CD34^+$ doses results in greater likelihood of rapid engraftment (Figs. 102.4 and 102.5).[29] Lower doses of $CD34^+$ cells appear satisfactory for nonablative regimens.

Patients who receive a dose of $CD34^+$ cells above a certain threshold will engraft. At lower doses of $CD34^+$ cells, considerable heterogeneity occurs in engraftment speed, especially for platelet engraftment. Why this heterogeneity exists is not known, but it may reflect a weakness in the correlation between $CD34^+$ cells and the cells responsible for engraftment, a greater heterogeneity of $CD34^+$ subsets collected, or perhaps simply a greater degree of error in the measurement of $CD34^+$ cells at the lower cell concentrations. As the dose of $CD34^+$ cells increases, the engraftment kinetics becomes both more rapid and more consistent for the population studied.

Subset analysis of $CD34^+$ cells may improve the accuracy of predicting neutrophil and platelet engraftment kinetics but does not appear to predict engraftment failure enough to be of clinical utility. Pecora and colleagues[30] reported that the quantity of $CD34^+CD33^-$ cells infused was identified as an independent factor predictive of engraftment kinetics. Dercksen and colleagues[7] reported better correlation between the number of $CD34^+CD33^-$ cells and time to granulocyte engraftment, and between the number of $CD34^+CD41^+$ cells and time to platelet engraftment than found with the overall number of $CD34^+$ cells. Coexpression of adhesion molecules is also predictive of hematopoietic recovery, with the same pathways important for both mobilization and homing of HSCs. Given the limited range in recovery times when adequate numbers of $CD34^+$ cells are collected and infused, however, this additional information is currently of limited clinical value.

$CD34^+$ cell dose is also predictive of outcome of allogeneic PBSC (and marrow) transplantation. Higher $CD34^+$ cell doses result in better neutrophil and platelet engraftments after either related or unrelated donor transplantation and may correlate with better survival after bone marrow transplantation, but may also be associated with the development of more chronic GVHD.

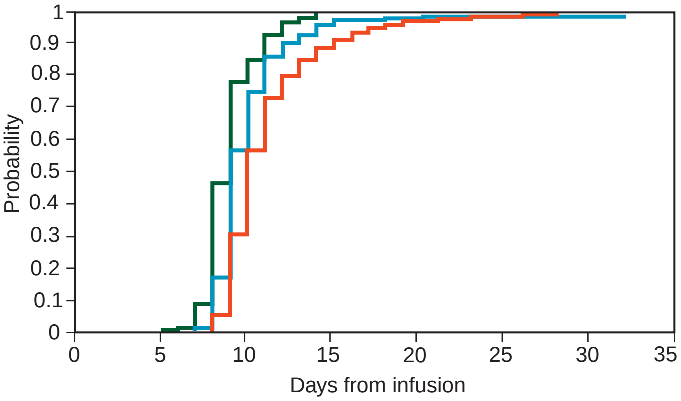

Figure 102.4 Kaplan–Meier probability of achieving ≥0.5 × 10^9 neutrophils/L for <5.0 × 10^6 *(red)*, >5.0–10.0 × 10^6 *(blue)*, and >10 × 10^6 *(green)* CD34$^+$ cells per kilogram (P = .0001). *PBSC*, Peripheral blood stem cell. *(From Weaver CH, Hazelton B, Birch R, et al. Cord Blood

Similar to bone marrow, total nucleated cell count is normally used as a surrogate for the stem cell content of the UCB product because the definition of adequate CD34$^+$ cell dose for engraftment is yet to be well defined. However, CD34$^+$ cell content has been correlated with engraftment, and CD34$^+$ cell count is now a routine component of UCB product quality control. It was also proposed that the HSC in the cord blood are more primitive than marrow and PBPC products and therefore may not express CD34 antigen well.

Tumor Contamination

The probability that tumor cell contamination of HSC product could contribute to relapse was demonstrated by Brenner and colleagues[31] in studies involving the autologous transplantation of genetically marked marrow cells, as well as in individual case reports describing the transmission of malignancy to allogeneic recipients from donors with occult disease at time of harvesting. Sensitive immunocytostaining techniques, clonal assays, flow cytometric analysis, and polymerase chain reaction amplification of malignant genetic material detect tumor cells in the autologous PBSC components of many patients with a variety of malignancies. In general, the incidence of contamination (number of patients with positive components) and the level of contamination (number of tumor cells per number of normal cells) is much less for PBSCs than for marrow products.

The presence of tumor cells at the time of collection or persisting after ex vivo processing may correlate with the extent of systemic disease or the chemotherapy sensitivity of disease at the time of cell collection. Whether patients transplanted with autologous PBSCs have a lower relapse rate compared with patients receiving bone marrow is not well defined, and appropriate phase III studies of this question will be difficult to design and enroll with patients in light of the other well-defined advantages of PBSC transplantation. In a retrospective study, Sharp and colleagues[32] demonstrated similar probabilities of relapse-free survival in recipients of PBSCs or marrow components if the components were free of lymphoma cells. In that study, patients with marrow involvement by lymphoma were assigned to transplantation with PBSCs. The authors concluded that PBSC transplantation is a sensible approach to the patient with overt marrow involvement. However, Brugger and colleagues[33] demonstrated that patients with breast cancer involvement of the marrow at the time of chemotherapy mobilization were likely to mobilize tumor cells into the blood. The most disturbing finding of this study is that the tumor cells were detected in the peripheral blood at the same time as CD34$^+$ cells. Similarly, Pecora and colleagues[34] found a relationship between the ability to detect tumors in PBSC components and in bone marrow samples, but they also found a higher incidence of positive PBSC components for patients who required greater numbers of apheresis procedures to achieve the target dose of CD34$^+$ cells. Investigators at the Johns Hopkins Oncology Center found no difference in the incidence of tumor contamination of PBSC components between patients treated with chemotherapy and cytokines and those treated with cytokines alone.[35] Ex vivo purging of tumor cells from PBPC products has not been shown to reduce the risk for relapse after autologous transplantation, either because the techniques are not adequate in depleting minimal residual disease or because patients relapse primarily from endogenous disease surviving the pretransplant conditioning regimen. Patients with marrow involvement may benefit from several cycles of debulking (in vivo purging) chemotherapy before collection of HSCs, with the caveat that extensive chemotherapy will also decrease the subsequent yield of PBSCs. Tumor cells in the HSC inoculum likely will not benefit the patient, but until further data demonstrating a deleterious effect on transplant outcomes are available, it is advisable that reports of tumor contamination in the collections for individual patients be interpreted with caution.

Microbial Contamination

Bacterial culture is an essential quality-control component and it is used to identify errors and breakdowns in manufacturing technique. Skin flora are the bacteria usually isolated, and infusion of culture-positive HSC products is generally without clinical sequelae, although serious infections have occurred after infusion of HSC products contaminated during processing. Culture-positive products need not be automatically destroyed. Any decision regarding the disposition of a culture-positive HSC product must be made by the patient's transplant physician after considering the type of contamination, the anticipated risks from use of the component, and the ability to replace the culture-positive product(s) in a timely manner.

The incidence of culture-positive PBSC components is considerably less than that for marrow. The actual incidence of contamination for all HSC products is likely several times higher than reported, however, because most laboratories will culture only a very small volume of product (≈1 mL). In a retrospective review of 2935 HSC products processed and transplanted at one center, positive microbial products were reported for 1.3% of bone marrow products, 0.7% of PBSC products, and 2.0% of UCB products. Coagulase-negative

Staphylococcus and *Bacillus* species accounted for 23 of the 38 positive cultures, but *Escherichia coli*, *Klebsiella pneumonia*, and *Pseudomonas cepacia* were cultured from one product each. The recipient of the *Pseudomonas*-contaminated product subsequently died of complications of *Pseudomonas* sepsis, but no adverse sequelae could be documented for any of the other 34 recipients of culture-positive products. The highest rate of contamination occurred in the UCB products collected for related donor transplantation (5 out of 18, 27.8%), likely a reflection of the collection techniques in place at the time, and illustrating the need for strict quality control in the collection and processing of HSC products.

CHAPTER 103

GRAFT ENGINEERING AND CELL PROCESSING

Adrian P. Gee

It has been more than 70 years since allogeneic hematopoietic stem cells (HSC) were first transplanted to human recipients in the form of bone marrow. Since that time, the source of HSC has widened to include autologous bone marrow, growth factor mobilized peripheral blood progenitor cells (PBPCs), umbilical cord blood, and more. In parallel, there has been the development of other cellular therapies to treat a variety of diseases (such as the use of T cells genetically modified to express a chimeric antigen receptor (CAR) for the treatment of leukemias)[1] and mesenchymal stromal cells (MSCs) to treat or prevent graft-versus-host disease (GVHD).[2] This chapter provides a general overview of how these cells are prepared ex vivo, tested, and released for clinical use. Preparation procedures range from the simple depletion of plasma or incompatible erythrocytes from HSC grafts to complex genetic modifications of other cells using viral vectors to induce tumor-associated antigen specificity.

The rapid development of cellular administrations for therapeutic applications has attracted the interest of regulatory authorities (e.g., the Food and Drug Administration [FDA] in the United States). Understanding the relevant regulations is critically important when undertaking the manufacture of these types of products.

REGULATORY ISSUES WITH CELL PROCESSING

In response to the increase in the use of therapeutic cell products, the FDA, and other national regulatory authorities, have had to develop a relevant regulatory strategy to cover these products. The approach used by the FDA, and some other agencies, has been to develop a risk-based method (Table 103.1). This is based on an assessment of the relative risks posed broadly by the collection of the initial cells, their ex vivo manipulation and storage, and their administration to the recipient. Good Manufacturing Practices (GMP) regulations have existed for some time and are applied in the drug field, primarily in the preparation of small molecules. This was extended to certain cellular therapy products when these were classified as drugs for regulatory purposes. The applicable GMP regulations appear in Title 21 of the Code of Federal Regulations, primarily in Parts 210/211.[3] They cover all aspects of manufacturing, testing, packaging, storing, releasing, and distributing drugs. Recognizing that these regulations were probably overkill for experimental cellular therapeutics being developed by an academic institution, the FDA published a guide indicating the level of GMP compliance required for products to be used in Phase 1 clinical trials.[4] Simultaneously, the Agency recognized that there were certain products whose preparation and use posed a substantially lower risk (e.g., PBPC) since their collection was straightforward, their ex vivo manipulation was simple and their clinical use did not result in adverse events, and was of clinical benefit. As a result, in 2005 they published Good Tissue Practice (GTP) regulations as a part of 21 CFR Part 1271 (Human Cells, Tissues, and Cellular and Tissue-Based Products [HCT/Ps])[5] to cover the preparation of these products. These were established nominally to prevent the introduction, transmission, and spread of communicable diseases by HCT/Ps. This was based on the presumption that most post-transplant infections and admissions to intensive care units were attributable to the administration of contaminated products. The validity of this assumption is open to question. GTP regulations provide a framework for screening, performing ex vivo processing, storing and distributing HCT/Ps, and providing the FDA with an overview of current activities by requiring an annual registration of collection and processing facilities. The Part 1271 regulations effectively filled a gap in the law that had left unregulated HCT/Ps that were minimally manipulated (e.g., were not cultured ex vivo, genetically modified, activated ex vivo), intended for homologous use, or not combined with another article (e.g., a matrix or scaffold) for administration. Minimally manipulated HCT/Ps should not exert a systemic effect and should not be dependent on the metabolic activity of living cells for them to function. If this was not the case, then the cells should be for autologous use only, for use in a first- or second-degree blood relative, or in reproductive use. Cellular products that fall into this classification are Type 361 products. The Part 1271 regulations do not apply to vascularized organs for transplantation, whole blood, blood components, or minimally manipulated BM for homologous use that is not combined with another article. This means that traditional marrow-derived hematopoietic stem cell transplants (HSCT) do not fall under FDA regulations and that these procedures are currently considered a practice of medicine.[5] Products that fall under IND regulations are referred to as Type 351 products. These are cells that have been cultured ex vivo and transduced or activated ex vivo and, therefore, are more-than-minimally manipulated. The facility processing these cells is required to operate under GMP.[3] These regulations were developed to ensure that products are prepared under a controlled and auditable process that ensures their safety, purity, and potency. As indicated previously, the agency has recognized the differences between products prepared for a phase 1 clinical trial[4] and, therefore, the application of GMP to cellular therapy products follows a continuum, such that as the trial proceeds, the expectation is that implementation of GMP will become more rigorous, such that a phase III product would be extensively characterized and manufactured using a fully validated process.

Implementation of Part 1271 regulations has impacted the "routine" laboratory that prepares cells primarily for HSCT. Laboratories that use cells other than bone marrow (BM) now must register annually with the FDA; ensure that donors meet eligibility requirements (or document why non-eligible donors are used); and manufacture, store, and distribute the cells under GTP. If a laboratory has previous experience manufacturing products under GMP conditions, it will already be familiar with most of the features of GTP. Generally, these cover personnel, procedures, facilities, environmental control and monitoring, equipment, supplies and reagents, recovery, processing and process controls, process changes, process validation, labeling controls, storage, receipt, pre-distribution shipment and distribution, records, tracking, and complaints. Implementation of the components of GMP and GTP operations is a time-consuming process that requires the development, implementation, and maintenance of numerous components and generates a considerable volume of documentation. Professional societies, such as the Foundation for the Accreditation of Cellular Therapy (FACT)[6,7] and AABB (formerly the American Association of Blood Banks),[8] have developed standards and an accreditation process that takes into account GTP/GMP regulations and provides a framework around which compliance can be built.

In the United States, cord blood is a licensed product, and facilities that prepare and bank cord blood are required to obtain a Biologics License. This allows the manufacturer to introduce, or deliver for introduction, a biologic product into interstate commerce (21 CFR 601.2). There are professional standards that address cord blood collection, manufacturing, and use.[9]

Central to both GMP and GTP regulations is the establishment and maintenance of a quality program. This quality program must ensure that the appropriate regulations are being followed on an

ongoing basis, that mechanisms are in place for detecting, reviewing, and remediating errors and deviations from regulations, policies, and procedures, and that an audit program will be developed, implemented, and maintained. Activities performed by the quality program must be documented, and the program should be staffed by individuals who are not involved in the hands-on manufacturing of products.[10]

Holders of INDs must provide the agency with an annual report on the protocol, including a listing of the products administered and those that have been prepared but not used. In addition, cell processing facilities should be prepared to assist the IND sponsor by providing information on products that have been associated with severe adverse reactions in the recipients and whether these were attributable to product quality. For Type 361 products, the facility must, as Biological Product Deviations, report any contaminated products that have been administered to a patient.

PROFESSIONAL STANDARDS

The two major accrediting organizations in the United States for cellular therapies are FACT and AABB. Whereas FACT offers accreditation for collection, processing, and clinical use of cellular therapy products,[6,7] the AABB focuses on collection and laboratory processing.[8] Both organizations inspect based on standards that are published every 18 months to 3 years. In the case of FACT, the standards are published in collaboration with the Joint Committee on Accreditation in Europe (JACIE). FACT also publishes separate standards that cover cord blood banking (in collaboration with NetCord)[9] and for Immune Effector Cells. Both organizations have worked to harmonize their standards with American, Canadian, Australasian, and European regulatory agencies; therefore, accreditation by either organization is of great assistance on the pathway to regulatory compliance. Several other professional organizations accredit particular aspects of operations within the cell processing facility. These include the College of American Pathologists (CAP), which accredits general laboratories and hematology and flow cytometry facilities, the American Society for Histocompatibility and Immunogenetics (ASHI), and the European Federation for Immunogenetics (EFI), which accredit histocompatibility testing laboratories. Some organizations, such as CAP and StemCell Technologies, also provide proficiency testing services for laboratory staff.

MANIPULATION OF HEMATOPOIETIC STEM CELL TRANSPLANTATION PRODUCTS

Hematopoietic grafts are manipulated in vivo to remove an unwanted component that may cause adverse effects or to enrich the desired population, such as HSC.[10,11] As discussed previously, the degree of manipulation may determine the regulations under which the product is manufactured and handled. The FDA defines minimal manipulation as processing that does not alter the relevant biologic characteristics of the cells or tissues. This includes procedures such as RBC, plasma depletion, and cell selection using an approved device. By contrast, more-than-minimal manipulation would include activities such as culture ex vivo, genetic modification, and ex vivo activation. As stated previously, manufacturers of minimally manipulated products would follow GTP regulations,[5] whereas products that are more-than-minimally manipulated would fall under GMP regulations.[3]

Routine Minimal Manipulation for Volume Reduction or ABO Incompatibility

The most widely used form of manipulation in the hematopoietic progenitor cell (HPC) processing facility probably is the removal of erythrocytes and plasma to overcome incompatibility between donor and recipient (Table 103.2). This process is performed using techniques that were developed by the blood banking industry.

Plasma depletion to remove donor antibodies that may react with recipient cells is achieved by centrifugation of the graft, usually in a transfer pack, at approximately 2000 g for 10 minutes at ambient temperature. The pack is then placed in a plasma expresser, which compresses the product bag so that plasma can be forced out and into a separate collection bag. Plasma depletion can also be used to reduce the volume of ABO-compatible grafts when the donor is larger than the recipient.

Erythrocyte depletion removes incompatible donor erythrocytes that would stimulate a reaction by the recipient upon administration. Most facilities establish a maximum volume of incompatible RBCs that can be infused with HPC; exceeding this limit can result in hemolysis and a transfusion reaction. Depletion of erythrocytes can be achieved most simply by centrifugation at approximately 3000 g for approximately 10 minutes at ambient temperature. The leukocyte-rich buffy coat is then collected from the interface between the plasma layer and the RBCs.

Erythrocyte depletion can also be achieved by sedimenting erythrocytes using hydroxyethyl starch (Hetastarch). This promotes RBC sedimentation by the formation of erythrocyte rouleaux. The hematocrit of the product is first adjusted to ~25% by the addition of normal saline, and 6% Hetastarch (Hespan) is added at a volume:volume ratio of 1:6 to 1:7. Sedimentation can be performed under gravity or accelerated by centrifugation.

A more rigorous erythrocyte depletion is achieved by centrifugation of the collection on a Ficoll-Hypaque density gradient. The cells are layered onto a density gradient cushion of Ficoll-Hypaque and centrifuged at 400 g for approximately 30 minutes. The mononuclear cells collect at the interface and are removed and washed before use. This process depletes erythrocytes, platelets, and granulocytes. The overall nucleated cell recovery is lower than with other techniques in which granulocytes are retained.

Automated devices are available for preparing buffy coats and density gradient-enriched cells. For larger volumes, the COBE 2991 Cell Processor from Terumo can be used. This requires a minimum volume of 150 mL RBCs for operation and may therefore not be suitable for pediatric processing. It is capable of preparing buffy coats and density-separated cell preparations using a functionally closed disposable set.

The COBE Spectra from Terumo is commonly used to collect PBPC by apheresis. The device is also less widely used in the processing facility to enrich mononuclear cells from BM.

For smaller starting volumes, the Sepax device from Cytiva (formerly GE Cell Therapy) (Fig. 103.1A) can be used. It has found widespread application in cord blood banks for buffy coat preparation (with or without the addition of hydroxyethyl starch) and has also been used for volume reduction of PBPC collections, density gradient separation of BM, and cell washing. The device has a small footprint, uses functionally closed disposables, and provides a printout of operations.

The AXP II System for cord blood processing is available from Thermogenesis. The device is designed for enriching mononuclear cells from cord blood that are transferred to the processing set, which is then placed into the AXP device. This fits into a centrifuge bucket, and during spinning, the red and mononuclear cells are collected into separate bags, and the plasma is retained in the processing set. The PXP System performs a similar procedure on marrow harvests. Both devices provide closed sterile systems, and each system comes with software that enables data tracking to assist with regulatory compliance.

TABLE 103.2 **Processing Performed to Address ABO Incompatibilities Between Hematopoietic Stem Cell Donors and Recipients**

Recipient ABO Type	Donor ABO Type	Type of Processing
ABO identical	ABO identical	No special processing required
A or B	AB	RBC depletion
O	A/B/AB	RBC depletion
A	B	RBC + plasma depletion
B	A	RBC + plasma depletion
Antibody to RBCs	N/A	RBC depletion
A/B/AB	O	Plasma depletion
AB	A or B	Plasma depletion

N/A, Not applicable; *RBC*, red blood cell.

Purging of Autologous Grafts

Autologous HPC can be used for recipients lacking a human leukocyte antigen (HLA)-matched related or unrelated donor. It has been proposed that occult viable tumor cells collected with the graft and returned to the patient could act as a source for disease relapse. Gene marking studies have supported this hypothesis. As a result, much effort has been exerted to develop methods for the ex vivo detection and removal of tumor cells from autologous grafts (Table 103.3). Techniques have included incubation with chemotherapeutic drugs, such as 4-hydroperoxy cyclophosphamide (4-HC), photosensitizing agents, and antisense oligonucleotides. Alternatively, tumor-directed monoclonal antibodies (MAb) can be used to identify the cells and effect their removal. The MAb-coated tumor cells can be eliminated by the addition of serum complement or by capturing them on a solid phase, such as a column matrix, a plastic sheet, or magnetic particles. These particles may be large (5 μm diameter—Dynabeads, Invitrogen), so they can be collected with the attached tumor cells in a standard magnetic field. The matrix material may be much smaller, such as iron-dextran nanoparticles (Miltenyi Biotec

[a]4-Hydroperoxycyclophosphamide.

Bergisch Gladbach, Germany) or ferrofluids (Ferrotec Santa Clara, CA), which coat the cells. These are then collected on a metal matrix placed in a field generated by permanent magnets. Such systems are capable of depleting 4 to 6 logs of tumor cells from a graft. However, even at such high efficiencies, and given the limits of our ability to detect residual tumor cells, the clinical value of purging autologous grafts is debatable. There has also been a decline in interest in purging techniques because of the potential benefits of a graft-versus-tumor (GVT) effect detected in recipients of allogeneic grafts.

T-Cell Depletion of Allogeneic Products

T cells in HPC grafts have the potential to cause severe or lethal GVHD or exert a beneficial GVT effect.[12] Considerable work has been done to determine whether or not these opposing effects are produced by distinct subpopulations of T lymphocytes. This would allow ex vivo manipulation of allogeneic grafts to remove differentially the GVHD-producing T cells while sparing those that mediate GVT responses. Various subpopulations of T cells have been identified as candidate effector subpopulations; however, there is still no widespread consensus as to which subsets should be targeted.

Methods are available for Pan-T cell elimination from grafts using approaches similar to those used for purging tumor cells (see Table 103.3). Early techniques included the use of soybean agglutinin to aggregate the majority of non-progenitor cells and the rosetting of sheep erythrocytes with T cells to facilitate their removal. Although successful, these techniques are not “FDA friendly” and do not offer the specificity that likely is required to engineer T-cell subpopulations in allogeneic grafts.[13–15] This is possible by using MAb directed toward the antigens that currently are used to identify T-lymphocyte subpopulations. The target population then can be removed with high efficiency using immunomagnetic separation, as described previously for purging autologous grafts. The challenge remains to identify the appropriate target T cell populations and to source clinical-grade MAb for these procedures. Several potential target antigens have been identified and separation techniques implemented. They range from pan–T-cell depletions using MAb to CD3 and CD2, depletions of helper and cytotoxic T cells using MAb against CD4 and CD8, to stimulation and removal of alloreactive populations by targeting activation antigens. In addition, methods have been developed for the selective manipulation of natural killer (NK)[16] cells, natural killer T (NKT) cells,[17] myeloid suppressor populations, and MSCs for administration to stem cell transplant recipients to prevent or treat GVHD.

Efforts have recently focused on the depletion of αβ-positive T cells from the graft. This spares the donor-derived alloreactive NK and γδ T cells, which may provide a tumor-directed response. Promising early clinical results have been obtained using this approach. Twelve patients received marrow or PBPC grafts depleted of ~4 logs of αβ T cells, and all were alive at 3 months, and after 1 year, two had died. There was no severe GVHD (grade III to IV) post-infusion. A systematic review of the impact of γδ cells on the outcome of transplants concluded from 11 studies (919 patients), with a median follow-up of 30 months, that high γδ numbers were associated with lower relapse, fewer viral infections, and higher overall and disease-free survivals; however, no association was found between high γδ numbers and GVHD incidence.

Regulatory T Cells

A different approach for GVHD is to administer T_{reg} cells post-transplant to prevent and treat GVHD. A first-in-man clinical study was performed using in vitro expanded T_{reg} from partially HLA-matched third-party umbilical cord blood units that were administered to 23 patients receiving double cord blood transplants. Results were compared to 108 historical controls. No T_{reg} acute toxicities were seen, and there was a reduced incidence of grades II-IV acute GVHD but since this was a Phase 1 study, it was not designed to demonstrate efficacy. Later studies support the finding that donor T_{reg} infusions early after transplant can prevent GVHD after allogeneic transplantation. There are several questions still to be addressed. These include the source of T_{reg} cells (cord versus peripheral blood—cord blood generally yields cells of a higher purity but lower numbers); whether the cells should be expanded in vitro before use; the best method for their purification; and the best conditions for expansion.

T_{reg} represents a rare cell population whose phenotype cannot be categorically defined. They are generally enriched using their expression of CD25, sometimes incorporating prior depletion of C8 and CD19-positive cells. This leads to an enrichment of $CD4^+CD25^+FOXP3^+$ cells which can be further increased to 87% purity by further in vitro expansion. The optimal method for enrichment appears to be the separation of $CD4^+CD25^{hi}CD127^{lo}$ cells. Peripheral blood T_{reg} cells can be effectively expanded in vitro by stimulation with CD3 and CD28 MAb and high concentrations of IL-2. Alternatively, artificial antigen-presenting cells (APCs) primed with CD3 (and CD28) MAb have been shown to preserve FOXP3 expression while achieving cell expansion. Expansion of cord blood T_{re} can be further improved by using APC additionally primed with OX40L or 4-IBBL. Rapamycin can also be used to enhance TGF-β-dependent FOXP3 expression and to limit the activation and expression of effector T cells. It should be noted that cryopreservation of T_{reg} may impair their function.

Positive Selection of Progenitor Cells

Methods that eliminate or physically remove either T cells or tumor cells from grafts are referred to as *negative selection techniques*. They are affected by variables such as target antigen expression, the sensitivity of detection technologies for quantitating separation efficiency, and other technical hurdles. These may be difficult to control in order to achieve the ideal composition of the graft, and the target level of residual T cells, or T cell subsets, remains to be established. A dose of 10^5T cells/kg is generally regarded as the goal to minimize the risk of GVHD while facilitating engraftment. There are also no approved devices for negative selection, so these types of procedures must be performed under an IND.

For many years, the goal was to replace the negative selection with a procedure in which HPC populations could be enriched by positive selection. This would effectively deplete T cells, or tumor cells, from allogeneic and autologous grafts, respectively. The problem was the lack of a method for identifying the target HSC until the CD34 antigen was identified on a small population of progenitor cells, including the pluripotent cells required for hematopoietic transplantation. The subsequent availability of MAb directed against this antigen made possible the development of techniques for the enrichment of these cells. Immobilization of the antibodies on a matrix (e.g., plastic sheets),cellulose, and magnetic particles were used as the primary approach, and several devices were commercially developed (see Table 103.3). The first to achieve FDA approval for use with apheresis products were the Baxter Isolex 300i, which used Dynal 5 μm magnetic beads as the separation modality and released CD34$^+$ cells from the beads using a competitive binding peptide. This device was taken over by Nexell, which ultimately went out of business in 2002.

The alternative is the CliniMACS system (Miltenyi Biotec, Fig. 103.1C), which currently has regulatory approval in Europe, but still requires an IND for use in the United States for other than one specific indication (the depletion of T cells by CD34$^+$ cells selection for the treatment of acute myeloid leukemia). This uses anti-CD34 or anti-CD133 nanoparticles to effect separation. The labeling with and removal of unbound MAb reagent is performed manually. The CD34 reagent-treated cells are then processed on the device, where they are retained on a column located in a high-gradient magnetic field. Nonlabeled cells flow through the column and are collected in the negative fraction. The labeled cells are recovered from the column after several automated separations and washing cycles by removing the magnetic field. The nanoparticles remain on the CD34/133-positive cells; however, they are biocompatible and may be infused into the recipient. Recently the company has come up with REAlease nanoparticles that can be removed from the targeted cells, however, these are not yet clinically approved. The CliniMACS device normally achieves purities over 90% with yields of approximately 60%. This results in the passive depletion of 4 to 6 logs of allogeneic T cells or autologous tumor cells. The device may be used with a variety of MAb directed against antigens expressed by various types (T, B, and NK cells), potentially allowing it to be used as a platform for multiple types of graft manipulation.

Miltenyi has also introduced the Prodigy device (Fig. 103.1B), which can automatically perform many of the steps requiring manual intervention on the CliniMACS. Additional features provide the potential ability to fully automate the preparation of a variety of cellular therapy products (e.g., CAR-T cells) in a functionally closed system. The regulatory status of these devices should be discussed with the appropriate regulatory agencies before clinical use.

Positive selection techniques may, however, passively deplete from the graft certain cells that could be of potential benefit to the recipient. These include some stromal elements, GVT-mediating T cells, and other populations that may facilitate engraftment. As our understanding of the identity of these populations improves, it may be possible to recover them from the normally discarded negative fraction and add them back to the CD34$^+$ cells or to administer them in the post-transplant period as donor leukocyte infusions).

Table 103.3 lists various methods for manipulation of HSC grafts to achieve tumor removal from autologous products and T cells depletion by HPC enrichment.

EVALUATION OF MANIPULATED ALLOGENEIC GRAFTS

Most allograft engineering has focused on T-lymphocyte depletion and has emphasized quantitative versus qualitative removal. The majority of allografts are infused immediately after preparation rather than after cryopreservation and storage. This restricts the types of assays that can be used to evaluate graft composition to those that have a fast turnaround since the implications of infusing large numbers of T lymphocytes can be severe or lethal. Therefore, it is important to have available methods that can rapidly enumerate the numbers of T lymphocytes within the graft. Early methods used detection of E-rosette–forming cells or manual immunofluorescence after staining with pan-T-lymphocyte–directed monoclonal antibody, however, most laboratories now rely on flow cytometry. This technology is widely used in routine clinical laboratories; however, some precautions must be taken when it is used for T-depleted allografts.

Flow Cytometry

Accurate enumeration of small numbers of target cells by cytometry requires rare event analysis. In this technique, large numbers of events must be accumulated and carefully analyzed if reliable data are to be obtained. This approach has been widely adopted for counting CD34$^+$ cells in unfractionated grafts but is often neglected when enumerating T lymphocytes in depleted grafts. The choice of MAb for detection of the T-lymphocyte population also is critical when using MAb-mediated depletion technology. The same MAb should not be used for both depletion and analysis because cells that became coated with the antibody during the depletion phase but were not effectively removed will be blocked from detection. However, they can be detected by adding an anti-immunoglobulin antibody conjugated to a fluorochrome different from the one conjugated to the T-lymphocyte–directed MAb. The most sensitive detection is achieved by using panels of non–cross-blocking anti–T-lymphocyte antibodies directed against a variety of epitopes.

It is important to include a viability stain in the analysis panel, especially when in situ elimination methods are used. In these cases, the depleted allograft may contain dead or dying T lymphocytes that will be detected by flow but may not contribute to post-infusion events. Suitable viability stains include propidium iodide and 7-aminoactinomycin (7-AAD). Analysis of cell viability after ex vivo depletion is not straightforward. Cell death may not be expressed immediately but develops in the hours or days after processing and infusion. Under such circumstances, the analysis of apoptotic cells by a combination of Annexin-V staining with 7-AAD may provide a more accurate estimate of cell damage. This approach can be used in combination with simultaneous staining for T-cell surface markers to provide additional information. In some cases, incubating the cells for a period before analysis is advisable (e.g., in the case of depletion by immunotoxins, cells require time to divide to manifest the toxic effects).

Functional Assays

Flow cytometry detects residual cells by their ability to bind MAb. Routine flow does not provide information on the functional capacity of these cells, which may be important when assessing the graft for its potential to mediate GVHD or GVT. Stimulation of cells with interleukin-2 (IL-2) and ex vivo culture also has been used to detect functional residual T lymphocytes. In some cases, this method has shown a correlation between the numbers of T lymphocytes in the cultured sample and the development of clinical GVHD in the graft recipient. Limiting dilution analysis also provides a sensitive method for detecting residual T cells. However, because of the complexity of the results obtained, its use as a routine procedure to guide immunosuppression is not recommended.

Release of Manipulated Grafts for Clinical Administration

A selection procedure that does not alter the biological status of the progenitor cells is not generally regarded as more-than-minimal manipulation by the FDA. This usually means that the procedure can be performed according to GTP regulations, and product release does not require a formal CofA. If, however, a commercial device is to be used in the procedure, this complicates the situation. For example, the Miltenyi CliniMACS device is approved as a Humanitarian Use Device for CD34 selection in certain patients in their first complete remission. The FDA recognizes that some investigators may use it in an off-label indication but has indicated that it will monitor sales to determine whether this is happening. Miltenyi also sells nanoparticles for the depletion of CD3/CD19 and TCRαβ T cells for research use only. If the system is to be used for clinical T cell depletion, it is advisable to contact the company and the FDA to determine whether an IND application is required.

If it is determined that an IND is necessary, the cells must be prepared under GMP regulations. These require that manufacturing be performed by trained staff following formal standard operating procedures. The chemistry manufacturing and control (CMC) section of the IND will specify how the product is prepared, the reagents and materials that will be used, and the criteria for the release of the product for clinical use. The FDA has published Guidances for preparing the CMC section of the IND application[18] and for the design of clinical trials of cell and gene therapy products.[19]

Release criteria are test specifications that are designed to ensure that the product is sterile and pure, and they may include assays for functionality. The specific tests for sterility and purity that have been approved by the FDA are described in 21CFR 610.12. In the normal release mechanism for a cellular therapy product, the quality unit reviews the production records and issues a certificate of analysis (CofA). This document details the testing that was performed together with the test method, the testing laboratory, the specification required by the FDA, and the actual results obtained. Routine testing required for most cellular therapy products consists of aerobic, anaerobic, and fungal sterility; endotoxin levels (by Limulus amebocyte method [e.g., Endosafe from Charles River]); mycoplasma for ex vivo expanded cells (assayed by the culture method, by a validated polymerase chain reaction-based method [e.g., MycoTOOL from Roche Applied Science or by MycoAlert with FDA approval]); identity and purity (by flow cytometry and, in some cases, HLA typing); and, for products in later stages of evaluation, functionality (e.g., cytotoxic activity toward target cells or secretion of specific bioactive products). Products that have been transduced with a retroviral vector will also require testing for replication-competent viruses. The use of non-FDA-approved test methods should be cleared by the FDA at the IND application stage. Regulatory agencies also like to see some form of stability testing program that evaluates the stability of the cellular product over time in storage in the frozen state and when thawed for administration.

GTP products are not released using a CofA procedure. Fresh cells are usually administered at risk unless it is decided to perform a Gram stain for sterility. Normally a 14-day sterility test is still performed, and there must be an SOP in place to inform the recipient's physician if a positive result is obtained, identify the organism involved, and obtain antibiotic sensitivities. Other tests may also be performed, for example, endotoxin, immunophenotyping. In most cases, cryopreserved products should be able to undergo full release testing before administration.

CELLULAR THERAPY PRODUCTS

Many therapy products, including some that have been genetically modified, are being evaluated in clinical trials to determine their value in preventing or treating GVHD and for potential anti-tumor responses (Table 103.4 and Fig. 103.2). These include unmanipulated leukoinfusions from HPC donors,[13] cytokine-induced T cells, lymphokine-activated killer (LAK) cells, tumor-infiltrating lymphocytes (TILs,[20] T-regulatory cells, antigen-specific T cells,[21] mesenchymal cells,[2] dendritic cells [DCs], and NK cells[16]). Detailed accounts of the scientific basis for such studies as well as results of clinical trials are given in other chapters in this volume. This section focuses on processing and product evaluation issues.

TABLE 103.4 Immunotherapeutic Cells Frequently Used in Hematopoietic Stem Cell Transplant Recipients

Cell Type	Clinical Use
T regulatory cells	Prevention/treatment of GVHD
Mesenchymal stromal cells	Immunosuppressive effect (GVHD) Regenerative applications
NK cells, TIL cells, LAK cells, NKT cells	Anti-cancer response (Some for prevention/treatment GVHD)
CAR-T cells	Anti-cancer response
Antigen-specific T cells	Anti-cancer response Anti-virus response
Dendritic cells	Anti-cancer vaccines Antigen-presenting cells (unprimed)

Given that the frequency of tumor or viral antigen-specific T cells in most cases is considerably lower than that of alloreactive T cells, it is necessary to expand antigen-specific T cells ex vivo not only to enhance antitumor activity but also to try to separate GVHD from GVT effect.
CAR, Chimeric antigen receptor; *GVHD*, graft-versus-host disease; *LAK*, lymphokine activated; *TIL*, tumor infiltrating lymphocytes; *NK*, natural killer cells; *NKT*, natural killer T cells.

Donor Leukocyte Infusions

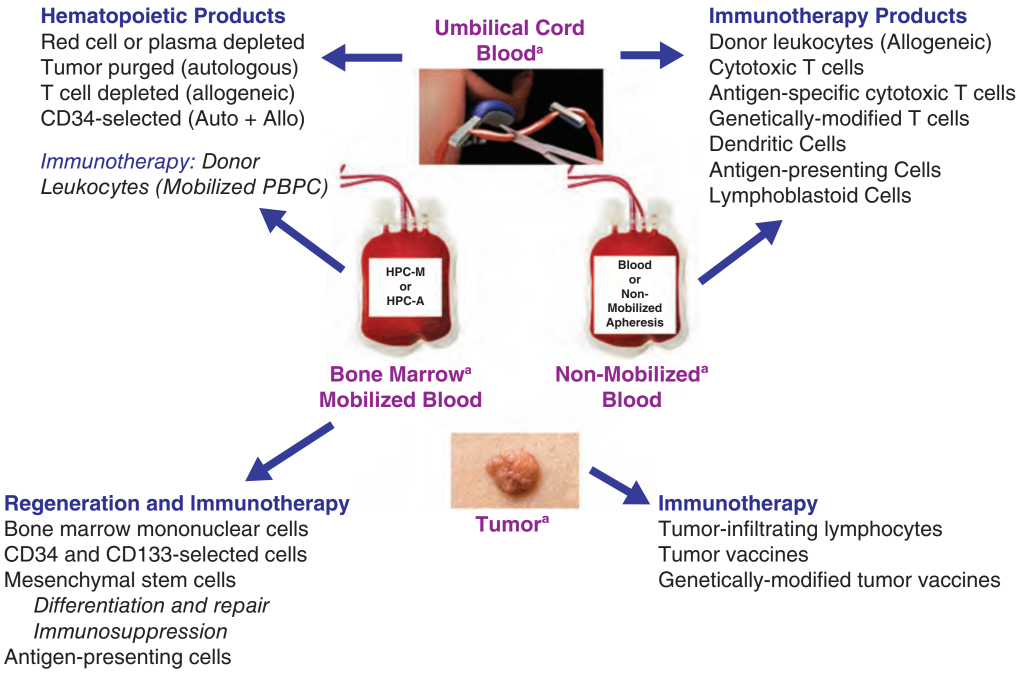
The ability of donor leukocyte infusions (DLI) to mediate antitumor responses was originally described in patients with chronic myeloid leukemia (CML) in hematologic relapse after allogeneic stem cell transplantation (SCT), but lymphomas and Hodgkin disease also are sensitive to the effects of DLI.[13] Remission rates of up to 80% have been reported in CML patients who relapse after transplant. DLI have also been used successfully in patients with myelodysplastic syndrome, and up to 90% of responses have been described in patients with Epstein-Barr virus (EBV)—associated lymphoproliferative disease. Moderate success has been achieved using DLI after relapse in other malignancies, such as acute myeloid leukemia (15% to 40%), low-grade lymphomas (≤60%), and metastatic multiple myeloma (40% to 60%). Fewer than 5% of patients with relapsed acute lymphoblastic leukemia respond to DLI alone. Although the etiology is unclear, the reason could be a lack of antigenic expression, downregulation of T-cell recognition molecules, or tumor burden at the time of treatment.

In practice, DLI are usually quantitated by their T cell (e.g., CD3, concentration, and frozen down in aliquots that provide a range of doses for the intended recipient). Initially, doses of 1×10^5 to 1×10^6kg are used, followed at intervals of 4 to 12 weeks with escalated doses, which may increase by 5- to 10-fold on each occasion. The timing of administration can be assisted by tracking the status of minimal residual disease or by mixed chimerism.

The regulatory situation for DLI is complicated and in transition. At present, non-manipulated DLI are classified as Type 361 products and fall under Part 1271 of 21CFR. It is possible that they will be reclassified as Type 351 products requiring an IND application. Currently, formal release criteria are not required; however, the normal practice is to evaluate T-cell content by flow cytometry and to test for sterility. This may be done by a Gram stain (used for immediate release) accompanied by 14-day culture-based methods. These provide results after the product has been infused. Formal procedures should be in place to inform the recipient's physician if a positive test result is subsequently received. The contaminant should be speciated and antibiotic sensitivities obtained and communicated to the physician. DLI that have been manipulated ex vivo in any way (e.g., by targeting them to specific antigens or by vector transduction, as described later) will be classified as Type 351 products requiring an IND. These products will require formal release testing as described previously for other cellular therapy products.

Allodepleted Cells

The major drawback of DLI is the significant risk of GVHD, which is the most important source of treatment-related mortality.



Hematopoietic Products
Red cell or plasma depleted
Tumor purged (autologous)
T cell depleted (allogeneic)
CD34-selected (Auto + Allo)
Immunotherapy: Donor Leukocytes (Mobilized PBPC)
Umbilical Cord Blood[a]
Immunotherapy Products
Donor leukocytes (Allogeneic)
Cytotoxic T cells
Antigen-specific cytotoxic T cells
Genetically-modified T cells
Dendritic Cells
Antigen-presenting Cells
Lymphoblastoid Cells
HPC-M or HPC-A
Blood or Non-Mobilized Apheresis
Bone Marrow[a] Mobilized Blood
Non-Mobilized[a] Blood
Regeneration and Immunotherapy
Bone marrow mononuclear cells
CD34 and CD133-selected cells
Mesenchymal stem cells
Differentiation and repair
Immunosuppression
Antigen-presenting cells

Immunotherapy
Tumor-infiltrating lymphocytes
Tumor vaccines
Genetically-modified tumor vaccines

Figure 103.2 CELL SOURCES FOR HEMATOPOIETIC TRANSPLANT AND POST-TRANSPLANT IMMUNOTHERAPY. *([a]From iStock Getty images.)*

A method for separating GVHD from the GVT effect is to selectively deplete alloreactive donor T cells ex vivo.[14,15] Selective allodepletion is performed by removing donor T cells that express activation markers after co-culture with non-leukemic recipient cells. Activation markers investigated include CD25 and CD69 and the increased sensitivity of activated T cells to photosensitizing dyes. Many phase I/II studies using immunotoxin directed against CD25 have demonstrated the feasibility of this approach, with accelerated reconstitution of virus-specific and total T-cell numbers and low rates of severe GVHD. Relapse rates remained high in this study, which probably reflects the high-risk nature of the patient population.

Potential recipients of allodepleted cells often receive a CD34-selected HPC graft. As a part of the CD34 selection process, a negatively selected population of cells that includes T cells becomes available. However, this fraction usually is not used as the source of cells for allodepletion. These cells usually have been obtained from donors who received granulocyte-macrophage colony-stimulating factor (GM-CSF) for mobilization of PBPC, and during processing for CD34 selection, they were exposed to an anti-CD34 monoclonal antibody. Therefore, it is preferable to obtain cells for allodepletion from a peripheral blood draw of the donor before administration of growth factor for mobilization. The T cell-enriched fraction usually is obtained by centrifugation on a Ficoll-Hypaque density cushion. The cells are washed and co-incubated with irradiated recipient mononuclear cells, which act as stimulators. A convenient source for stimulator cells is obtained by generating a cell line from the donor by infection of their peripheral blood mononuclear cells with a laboratory strain of EBV. The co-incubation step produces stimulation of alloreactive donor T cells with the resulting expression of activation markers, which then can be targeted to remove the alloreactive population. Methods for elimination include cytotoxic drugs (e.g., methotrexate), anti-CD25 monoclonal antibody conjugated to the toxin ricin, and immunomagnetic selection. All of the regulatory issues associated with the manufacturing and release of Type 351 products apply to allodepleted T-cell products. Release criteria include routine assays for sterility and purity. HLA typing may be included as a confirmation that the cells in the product are of donor origin. Functional assays may include a demonstration that the allodepleted cells fail to proliferate when cultured in a primary mixed lymphocyte reaction (MLR). If a suicide gene has been introduced (see below), testing will include demonstration that it can be efficiently activated.

Tumor-Infiltrating Lymphocytes

TIL are cells harvested from tumor sites (see Fig. 103.2),[20] which are expanded ex vivo with IL-2. As the cells are being expanded, increased tumor specificity can be achieved by pulsing the cells with tumor-specific peptides or transducing them with a retrovirus encoding a tumor-specific TCR. A major limitation is that patients must have pre-existing lymphocytes that can both respond to the tumor and be expanded ex vivo. Transferring these cells has led to tumor regression in 50% of lymphodepleted patients with metastatic melanoma.

Many methods have been developed for the isolation of TIL from tumors. They include mechanical disruption, enzymatic treatment, differential centrifugation approaches, and positive immunomagnetic selection. The method of choice depends on the type of tissue from which the cells are to be extracted and the availability of reagents, such as MAb, to enrich the T-cell population of interest. As with T-cell depletion of allogeneic grafts, the predominant effector TIL cell population is not fully characterized, and the availability of this information should facilitate the design of more effective separation techniques. A number of approved enzymes and centrifugation media are available, and several companies have suitable MAb that have been prepared under GMP conditions but have not been submitted for FDA approval.

The extracted cells are expanded ex vivo, usually starting in semi-open systems such as cluster plates. The initial populations may be tested in a cytotoxicity assay in an attempt to identify the effector population, which can then be selected for expansion. The expansion phase usually progresses through a number of types of cultures as cell numbers increase. These may involve growth in plates initially, progressing to T flasks and gas-permeable bags and on to hollow fiber and culture bag bioreactors. The culture medium contains IL-2 as the primary cytokine, although other agents alone and in combination may be used to promote the outgrowth of specific cell subpopulations.

Some investigators have used irradiated tumor cells to restimulate TIL during culture; others have performed selective separations to enrich the effector cells during expansion. Highly characterized tissue culture media, such as the serum-free lymphocyte medium AIM V, have been used for expansion. The goal is to use the simplest medium with the fewest additives that will support the growth of functional cells. When possible, the media should be free of animal serum and proteins to simplify the regulatory issues. However, the FDA is aware that complex media and serum combinations may be required to support the growth of some cell types and is willing to consider them, particularly if the cells can be washed into an approved excipient for administration.

Initiation of a phase I study using TIL or TIL subpopulations will not require complete characterization of the effector cell population, but some preliminary information should be available that allows quantification of the putative effectors for dosing purposes. In most cases, flow cytometric analysis will be used, and the target antigens may be pan–T-cell markers or specific combinations of T subset markers. When other constituents of the product may adversely affect the activity of effector cells, it may be necessary to set an upper limit for contamination by these cells in the clinical product. Most facilities perform some type of functional assay as a part of the release process, which in the case of TIL may be cytokine release or cytotoxic activity toward tumor cells of the appropriate histologic type.

Suicide Gene-Transduced Lymphocytes

Although treatment with DLI has led to remission in patients with the disease after HSC transplantation, unmanipulated cells also contain alloreactive T cells and can induce GVHD. The incidence of GVHD ranges from 55% to 90% and is associated with a treatment-related mortality rate of about 20%. Approaches that maintain the GVT effect while decreasing the incidence of GVHD have been evaluated and include transduction of donor T cells with a “suicide gene”.[22] Genes can be introduced into DLI or alloreactive-depleted cells to express the herpes simplex virus-1 thymidine kinase (HSV-tk). If GVHD develops, Ganciclovir is administered to the recipient, resulting in the suicide of the transduced donor leukocytes.

Alternative suicide genes based on the dimerization of Fas or Caspase-9 in the apoptotic pathway have been developed to circumvent the problem of immunogenicity of HSV-tk. The inducible Caspase construct also encodes a selection marker, such as CD19, that can be used to enrich the transduced population. If GVHD develops after administration of the Caspase-transduced cells, the suicide activation drug can be administered to the recipient to eradicate the transduced T cells by dimerization of Caspase 9 and activation of the apoptosis pathway. This approach is now also being used to control CAR-T cells administered post-transplant.

Antigen-Specific Cytotoxic T Lymphocytes

Two major prerequisites for generating antigen-specific cytotoxic T lymphocytes (CTL) are the identification of appropriate viral (in the case of EBV-associated lymphomas)[21] or tumor target antigens and the availability of suitable APCs. After being identified, CTL lines can be generated by co-culturing T cells with APC that express the target antigen. The lines are then expanded by re-stimulation with the antigen of choice and the addition of cytokines such as IL-2.

To generate antigen-specific CTLs, it is necessary to have a good source of APCs and a source of antigen to present to T cells. A variety of APCs have been evaluated, including fibroblasts, monocytes, and DCs, using different sources of antigen, including virus lysate or lysate of antigen-positive cells, peptides, or transduction of the APC, such as lymphoblastoid cells (LCLs) and DC with an immunodominant antigen. The use of lysates as the antigen source can be problematic because they are likely to be variable and difficult to standardize. Alternatively, many processing laboratories may not be experienced in handling virus and virus-infected cells.

Lymphoblastoid cells prepared using laboratory strains of EBV make excellent APCs for use in manufacturing EBV-specific T cells. They present EBV antigens efficiently, and they express high levels of co-stimulatory molecules. The typical procedure for generating the LCL is co-incubation with EBV derived from the tamarin B95-8 cell line. This line has undergone extensive testing and has been approved for use as a source of “clinical” EBV. The resulting LCLs are cultured in media containing acyclovir to eliminate any residual EBV. The LCLs are used to repeatedly stimulate T cells (as a mononuclear cell fraction of peripheral blood leukocytes), resulting in a population that is directed toward the immunodominant EBV antigens. These CTLs can be frozen while release testing is performed. They are delivered frozen to the bedside, where they are thawed and administered intravenously. Release testing consists of the routine tests described earlier for Type 351 products. For allogeneic CTL, functionality usually is assessed by cytotoxicity assays, which must demonstrate less than 10% killing of autologous blasts.

One limitation of this approach is that expanding of virus-specific T cells to achieve adequate dose levels is extremely time-consuming. All of these procedures require several weeks to generate APCs. More recently, accelerated methods of production have been developed. These include using direct T cell stimulation using mixtures of peptides for overlapping regions of the target antigen(s) (Pepmixes) and using disposable bioreactors that provide improved gas exchange, thereby markedly improving rates of T cell expansion.

An alternative strategy is to manufacture and bank third-party allogeneic antigen-specific CTLs with a range of HLA types so that an “off-the-shelf” product is available.[21] Anti-viral clinical responses have been described for patients who received partially matched allogeneic CTL. The generation of banks of CTL requires careful donor screening and HLA typing to allow at least partial matching with the intended recipient.

Chimeric Antigen Receptor T Cells

The use of T cells transduced to express CARs directed against tumor antigens has produced very promising results in clinical trials in CD19-positive leukemias and is now being evaluated for the treatment of solid tumors. The CAR often incorporates other moieties that are designed to dampen inhibitory signals from cancer or to amplify a beneficial immune response. CAR design is continuously evolving (Fig. 103.3). Initially, first-generation CARs were used, which included activating receptors such as CD8/CD3ζ. Second-generation CARs provided dual signaling combining activating and costimulatory signals. Third-generation CARs comprise more complex structures with at least three signaling domains, and fourth-generation receptors include a cytokine transgene.[23] Manufacture of these cells requires the preparation of an appropriate construct and delivery system (viral or non-viral vector) that is used to modify the T-cell population.[24,25] Traditionally, gamma retroviral or lentiviral vectors have been used for transduction. Transposases and RNA electroporation or cell surface conjugation are also being used to achieve transient CAR expression with the resulting CAR-T cells persisting for about two weeks.

There are numerous methods for preparing CAR-T cells involving the selection of different T cell subsets ($CD4^+$, $CD8^+$, γδ and αβ, naive, central memory, effector memory, virus-specific T cells, and a stem-like memory T cell). Magnetic separation methods are generally used for their enrichment, and expansion is achieved using a variety of cultural conditions. Several other cell types (e.g., NK-T) T_{reg}, and NK cells are also now being transduced to express CARs. Release testing is similar to that required for other gene-modified cellular therapeutics.

Analysis of Antigen-Specific T cells

Tetramer Analysis Enumeration of T cells bearing receptors for specific antigens can be achieved using tetramer analysis. Soluble versions of the heavy chain of major histocompatibility complex (MHC) molecules are first synthesized and adopt the appropriate conformation when a synthetic peptide representing the epitope is recognized by the T-cell receptor (TCR), and β2-microglobulin is added. The

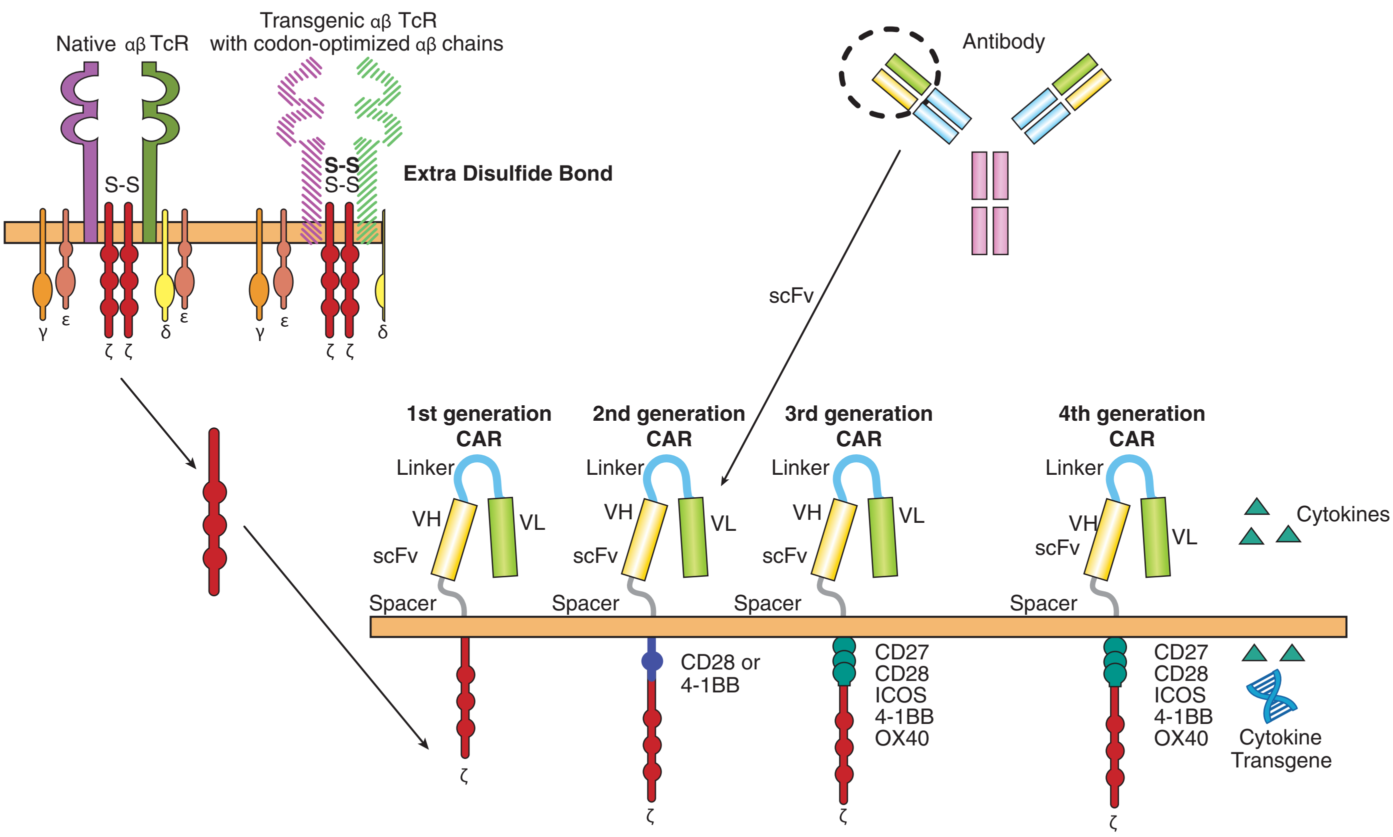

Figure 103.3 EVOLUTION OF CAR ANTIGEN RECEPTORS.

carboxyl-terminus of the MHC molecule is biotinylated, and four of these peptide/MHC—biotin complexes assemble into a tetramer when streptavidin is added. The streptavidin is tagged with a fluorochrome, therefore, T cells reactive with the chosen peptide—MHC complex become fluorescently stained and can be detected by flow cytometry.

Enzyme-Linked Immunosorbent Spot

Another approach is the use of an enzyme-linked immunosorbent spot (ELISpot) assay in which cells are stimulated to produce an analyte that is characteristic of their normal function. The cells are plated onto a surface that has been coated with an antibody directed against that analyte and incubated for a fixed period. The secreted analyte binds to this antibody, and the cells and any other unbound material are washed away. The surface is incubated with a biotinylated antibody directed against the analyte, washed, and incubated with alkaline phosphatase linked to streptavidin. After washing, the plate is incubated with a substrate solution. A blue-black precipitate will appear at sites where the analyte was produced, with each spot representing an analyte-secreting cell. The spots can be enumerated manually or by using an ELISpot reader.

These assays are not suitable for use as release tests because of their turnaround time, but they can provide retrospective information that may correlate with clinical outcomes.

Natural Killer Cells

NK cells are effectors from the innate immune system that also mediate antiviral and antitumor immunity. Studies have shown that haploidentical NK cells infused after lymphodepleting chemotherapy can have antitumor effects.[16] There are more than one thousand clinical NK cell trials completed or in progress. The majority are in the United States, followed by China, and are in use for the treatment of both leukemias and solid tumors.

NK cells can be prepared from Ficoll-Hypaque-enriched PBPC collections seeded into G-Rex bioreactors (Wilson-Wolfe Manufacturing) at 2 to 8 × 10^4 $CD56^+$ $CD3^-$ cells/cm^2. These are stimulated with K562 APC expressing mb15–41BBL at a 10:1 ratio of APC to NK cells. A simple positive selection with clinical scale immunomagnetic methods involving CD56 selection and CD3 depletion can be used to enrich NK cells from the expanded product.[26]

These procedures must be done under an IND because of the lack of commercially available devices and reagents for this indication. Recent evidence has suggested that cryopreserved NK cells have impaired functionality on recipients, in contrast to cells that are infused fresh. This poses an additional challenge to the manufacturer, who must coordinate testing and possible shipment of the fresh product. It is not clear whether the same findings may apply to other cell therapy products.

When preparing an IND application for NK cell enrichment, care should be taken to ensure that the MAb used for the selection, or depletion, are of the highest quality available. CofA for these reagents should be submitted with the IND application, and the agency probably will require detailed information on their manufacturing (i.e., to ensure that the process includes robust procedures for virus inactivation or removal). The same type of information may be required for any ancillary reagents (e.g., buffers and protein sources used to supplement buffers). Preclinical data demonstrating that the enrichment technique is effective should be provided and accompanied by data from clinical scale validation enrichments, providing evidence that the NK cells can be separated with acceptable viability, purity, and yield for the proposed study. The CMC section of the IND application should include information on the methods used to store, label, and administer the cells. Engineered APCs, such as the K562-mb15–41BBL cell line, if used to stimulate NK cells, should initially have been grown and tested as a Master Cell Bank, from which a Working Cell Bank is generated and tested for routine use.

Natural Killer T Cells

NK-T cells are innate-like CD1d-restricted T cells that recognize lipid antigens in a non-HLA-dependent manner and can rapidly respond to antigenic stimulation to produce large amounts of chemokines and cytokines, which can modulate both innate and adaptive immune responses.[17] Type I NK-T cells recognize α-galactosylceramide (α-GalCer), whereas Type II NK-T cells do not. Type II NK-T occurs with a higher frequency than Type I in humans. NK-T cells can kill CD1d-expressing tumor cells by direct cytolysis using perforin, granzyme B, Fas ligand, or TNF-α-mediated cytotoxic pathways. CD1d-bearing tumor cells are mainly myelomonocytic or of the B cell lineage. Type I NK-T murine cells have been generated ex vivo from CD34$^+$ cord blood cells using IL-15 and stem cell factor (flt-3 ligand).

Clinical trials using autologous NK-T cells transduced with a GD2-specific CAR (14 G.28.IL-15) vector and allogeneic third-party NK-T cells using a CD19 CAR vector construct that includes IL-15 and shRNA to reduce HLA expression are ongoing at Baylor College of Medicine. The cells are selected using the CliniMACS device and anti-NKT beads (Miltenyi Biotec). The selected cells are cultured with the irradiated negative fraction in the presence of α-Gal-Cer, IL-2, and IL-21 in G-Rex bioreactors (Wilson Wolfe), after which they are transduced with the retroviral vector and further expanded. Additional clinical trials are underway in China and Korea.

Dendritic Cells

DCs are powerful APCs that can be used in vitro or in vivo to elicit an immune response to the antigen they are presenting. A number of studies have evaluated tumor antigen-primed DCs for the treatment of hematologic malignancies and solid tumors.[27] Antigen-primed DCs are used to target T cells in vitro toward specific antigens. These cells then can be used therapeutically to eliminate viruses or tumor cells bearing that antigen. DC can be derived from BM or cord blood and mobilized and resting peripheral blood obtained from normal donors and patients. The typical procedure consists of enriching monocytes from the source material, which has been accomplished by plastic adherence or CD14-based immunomagnetic selection (or by depletion of CD19$^+$ B cells and CD2$^+$ T cells). An alternative approach is the use of elutriation to collect an enriched monocyte fraction from the donor. A purpose-built elutriation system for the collection of monocytes is available (the Elutra). This method also has been used successfully to enrich monocytes from cryopreserved mobilized apheresis collections.

The monocyte fraction can be cultured in polystyrene tissue culture flasks or gas-permeable bags in a culture medium containing IL-4 and GM-CSF to induce DC differentiation. This is followed by culture in a medium containing pro-inflammatory mediators to accelerate maturation. A number of supplements have been used during this phase, including CD40 ligand or poly(I:C), interferon-α, tumor necrosis factor-α, IL-6, IL-1α, and prostaglandin E_2. Some protocols add pro-inflammatory mediators at the initiation of the cultures rather than after induction of differentiation. One issue for manufacturers is finding clinical or GMP-grade cytokines and growth factors. Some sources are now available, and many manufacturers assist investigators by providing information on test procedures and stability information. Attempts have been made to expand DC in serum-free medium with varying degrees of success; improved growth and maturation have generally been obtained in the presence of human AB or autologous serum. Of note, minor changes in the composition of the culture medium and even in the type of vessel used for culture have been reported to affect the yield, phenotype, and functional activity of the resulting DCs. Cultured DCs have been effectively transfected using native tumor DNA or lentiviral or adenoviral vectors. The cells can be cryopreserved for later administration or use.

Assessment of DC product usually involves immunophenotyping (CD1a$^+$, CD80$^+$, CD83$^+$) and some type of functional assay (ability to generate an allogeneic T-cell response or response to a recall antigen as measured by proliferation assay) in addition to the standard release assays.

Mesenchymal Stromal Cells

MSCs are cells with multilineage potential that have shown efficacy in promoting engraftment and suppressing GVHD.[2] They are also being widely used in regenerative medicine and cancer immunotherapy applications,[2] where their mode of action is not well understood.[28] In vitro MSCs are capable of differentiating into bone, cartilage, cardiac and skeletal muscle, neuronal cells, adipose and connective tissue, and tendons. The cells are not inherently immunogenic and do not appear to be recognized by allogeneic T cells or NK cells. They express very low levels of MHC class II and intermediate levels of class I antigens. They appear to be able to suppress in vitro T-cell proliferation and function of both memory T and naive T cells and inhibit the development of monocyte-derived DCs in vitro.

A number of technical variables affect MSC culture and expansion ex vivo. They include culture medium, passaging density, serum type and concentration, population selection, culture vessel, and use of growth factors. To reduce some of this variability and decrease the cost of preclinical testing, the FDA often encourages investigators to adopt a manufacturing process that is in current clinical trials. The following is a basic procedure. MSCs usually are isolated from BM collected from the iliac crest. The cells are diluted, and the mononuclear fraction is isolated using a Ficoll-Hypaque density cushion. This fraction is plated into culture flasks to enrich adherent cells. The non-adherent population is removed after approximately 7 days of incubation. The adherent cells are washed and detached by incubation with trypsin/ethylenediaminetetraacetic acid (EDTA) (alternatively, Trypzean, a recombinant form of trypsin, can be substituted) and then cultured and passaged at weekly intervals. In a study designed to optimize culture conditions, the best results were obtained when cells were cultured in low-glucose Dulbecco modified Eagle medium (DMEM)based media containing 10% fetal bovine serum (human platelet lysate is now frequently substituted) and GlutaMAX instead of l-glutamine. The cells also proliferated better when plated at low cell densities (5000 to 10,000 cells/cm^2) in Falcon flasks. The use of basic fibroblast growth factor as a growth supplement was found to be effective; however, it caused HLA-DR induction and upregulated HLA class I expression. This did not affect the immunosuppressive capabilities of the cells. An increase in osteogenic and adipogenic potential was noted, but neurogenesis and engraftment support for CD34-positive cells were slightly suppressed. A number of media specifically designed for the culture of MSC are commercially available (e.g., PRIME XV from Irvine Scientific, STEMPRO MSC-SFM, a serum-free formulation from Invitrogen, and Mesencult, a basal culture medium from StemCell Technologies). Various investigators have reported success growing MSCs in serum-free media or using platelet lysate, autologous serum, or human AB serum as alternatives to fetal bovine serum. The traditional method for producing MSC is tissue culture flasks is laborious and involves many open procedures that could result in product contamination. An alternative method is to use a functionally closed, hollow fiber bioreactor, such as the Quantum from Terumo. In this system whole marrow is loaded into the reactor and the adherent cells attach to the fibers. Non-adherent cells are flushed from the fibers, which are perfused with the culture medium. Growth is monitored by glucose consumption and lactate production, and the flow rate of the medium is increased based on these readings. The cells are removed from the fibers by routine enzymatic treatment.

MSCs can be characterized by their expression of CD105, CD73, and CD90, and their lack of expression of CD45, CD34, CD14 or CD11b, CD79a or CD19, and HLA-DR. They must be plastic adherent under standard culture conditions and must be capable of differentiating into osteoblasts, adipocytes, and chondroblasts in vitro. Differentiation assays involve growing MSCs under conditions that promote differentiation along the specific pathway. For neurogenic differentiation, the medium contains linoleic acid, platelet-derived growth factor, and epidermal growth factor. Neural cells are identified by immunostaining with antibodies against tubulin BIII, synaptophysin, galactocerebroside, neurofilament M, and neuronal nuclei (NeuN). To assess adipogenic potential, the medium contains dexamethasone, isobutylmethylxanthine, and indomethacin. The lipid droplets in the generated adipocytes are visualized by staining with Sudan Black IV. Osteogenic differentiation is measured by culturing the cells in a medium containing dexamethasone, β-glycerophosphate, and l-ascorbic acid 2-phosphate. Calcium accumulation and alkaline phosphatase activity in the resulting cells are visualized by alkaline phosphatase/Von Kossa staining, and the osteogenic differentiation is measured as the percentage of mineralized area in the total cultured area.

The ability of MSC to suppress an MLR can be used as an indication of their immunosuppressive activity. A traditional MLR assay is used; however, in the test wells, the MLR is performed on a layer of MSC seeded the day before. The response, traditionally, is measured by uptake of tritiated thymidine. Numerous animal assays for MSC are available but are predominantly used in preclinical studies and are not useful as release assays. Release criteria consist of the usual assays for sterility, endotoxin, and mycoplasma, with immunophenotyping for the MSC population. Depending on the intended use of the MSC, the release process may require an assay showing potential for differentiation into a specific lineage or ability to suppress the immune response, such as in the MLR assay.

Cancer Vaccines

Tumor vaccines as an approach to inducing or stimulating immunity have been evaluated.[29,30] Various techniques have been tested, including the use of DCs pulsed with a tumor-associated antigen preparation and the use of the entire tumor cell as an immunogen, either unmodified or transduced with immunostimulatory genes, aimed at eliciting a broad-based, robust immune response.

From the manufacturing perspective, the autologous product is much more of a challenge because a stable tumor cell line must be isolated from each patient. This can be an extremely difficult process. Many isolated lines do not expand well in culture, or they change phenotype over time. In some patients, the line cannot be generated; other patients progress clinically before the vaccine is available and are excluded from the study. As a result, the autologous approach has a relatively high “failure rate.” The allogeneic cell line approach is technically easier because a line is selected before the study and can be used as the generic immunogen. This line must be tested extensively for infectious agents and should pass the FDA testing criteria for Master and Working Cell Banks. Scientifically, the drawback is that the selected line may not adequately express the antigen or range of antigens present on each patient’s tumor. In addition, the choice of immunostimulatory molecules that are expressed or enhanced by transduction of the cell line may not be those that would most effectively evoke an immune response. These products are relatively expensive to produce, involving not only the costs of testing the tumor cell line but also the expense of manufacturing and testing the vectors used for transduction. However, these are one-time costs because the same vaccine is used for all patients in the study.

Release testing of cellular vaccines involves testing for sterility, endotoxin, and mycoplasma, with immunophenotyping of the cells and some form of test demonstrating that the line has been effectively transduced (e.g., flow cytometry for CD40 ligand and IL-2 production in the examples described earlier). Because the product will be stored cryopreserved throughout the study and thawed for administration to each patient, the requirement for an ongoing stability study should be anticipated.

An alternative strategy is the administration of peptides identified from tumor-associated or tumor-specific antigens used in combination with a variety of cytokines (e.g. IL-2, Il-7), radiotherapy, checkpoint inhibitors, chemotherapy, or small molecules (e.g. tyrosine kinase inhibitors) to stimulate an immune response in the recipients.

FUTURE DIRECTIONS

The practice of hematopoietic transplantation has changed dramatically over the past 10 years as a result of an improved understanding of the immunological interplay between GVHD, GVT, and anti-tumor responses mediated by post-transplant cellular therapies. Access to transplants has been improved by using matched unrelated and haploidentical grafts and by the availability of cord blood banks. GVHD has been reduced by the administration of T_{reg} and MSC post-transplant, and efforts are underway to exploit GVT responses. A major development has been the successful use of CAR T cells to destroy leukemic cells, and work is in progress to target solid tumors. We have seen some of these cells approved as licensed therapeutics, marking a major step forward for cellular therapies. At the same time the regulatory environment has become more stable and has recognized the issues associated with the rapid development pathway associated with these new types of treatments.

For the research community and cell manufacturing facility, life has been made easier by the availability of GMP-grade reagents and new cell culture and separation devices. There are also rapid testing methods available for endotoxin and mycoplasma, simplifying the release of products for clinical use.

As our understanding of the immunology of transplantation and immunotherapy increases, it is likely that we will continue to see the development of even more effective therapies.

CHAPTER 104

PRINCIPLES OF CELL-BASED GENETIC THERAPIES

David A. Williams

The use of gene transfer to treat human diseases has now been demonstrated to be efficacious in a growing number of indications. Proof-of-principle successes in several monogenic diseases—both hematologic and non-hematologic—have been published and widely publicized in the past decade. The previous occurrence of serious adverse events in some trials related to insertional mutagenesis has stimulated the development of safer vector systems and the improved efficiency of gene editing methods at a clinical scale, particularly those using clustered regularly interspaced short palindromic repeat (CRISPR) technology, holds great promise in the near term. This chapter discusses the basic biology of vector systems applicable to blood diseases, the details of the application of gene therapy to blood diseases using specific trials as examples of this technology, and the modifications in vector systems driven by clinical experience that predict future trials. The chapter also discusses the evolving field of genome editing that is already being tested in clinical trials.

HEMATOLOGIC DISEASES, CELLULAR TARGETS, AND THE BASIS FOR GENETIC THERAPIES

Gene therapy is defined as the introduction of new genetic material into the cells of an organism for therapeutic purposes. Broadly speaking, two types of gene therapy can be envisioned. The introduction of genetic material into germ cells such that the new DNA can be expected to be passed into the gene pool. This is termed *germline gene therapy* and is currently banned in the United States and around the world. The potential for newer methods of genome engineering to be utilized in clinical applications (discussed later) has led to more recent calls for extending this restriction. In contrast, the introduction of new genetic material into specialized cells of the body with no risk of the new genetic material being passed onto subsequent generations is termed *somatic gene therapy*. The ultimate goal of gene therapy is to correct the phenotypic abnormalities of the targeted genetic disease by *replacement* of the defective gene in situ. Such gene replacement could be envisioned via a process termed *homologous recombination*. Homologous recombination in mammalian cells is widely practiced in laboratories, but up to now, has been relatively inefficient, although newer technology appears to overcome the previous limitations of efficient genome editing. Advantages of this approach would include a reduction in the risk of inadvertent disruption or dysregulation of expression of a critical gene sequence and regulated (appropriate level and distribution) expression of the normal (replaced) gene. However, the frequency of homologous recombination (in contrast to random chromosomal integration or even editing using non-homologous methods) in mammalian cells and primary tissues at a clinical scale makes therapeutic use of homologous recombination still somewhat impractical at this point. Methods to effect homologous recombination efficiency have improved in the past 5 years and may make this goal attainable in the future.

The requirements for successful application of our current gene transfer technology for the treatment of human diseases include knowledge of the abnormal gene sequence responsible for the disease phenotype and the availability of the corresponding normal gene sequence that can be packaged into current vector backbones for efficient recombinant virus production. In addition, the cells responsible for the disease phenotype must be identified and accessible for genetic manipulation. Finally, a means of introducing and expressing the correct gene sequence in cells such that the disease phenotype can be reversed is needed. Although effectively accomplished in the early 1980s in murine studies, this latter requirement encompassing both in vivo administration of DNA sequences and ex vivo cell manipulation has been more difficult to consistently meet in human applications using current gene transfer technology.

Since the early development of virus vectors, blood-forming cells have been used as one optimal target for ex vivo gene transfer studies. For this purpose, hematopoietic stem and progenitor cells (HPSCs) are isolated, manipulated in the laboratory and administered back to the patient. The advantages of these cells as targets of gene transfer are multiple. First, all blood cells are derived from a common progenitor cell, the hematopoietic stem cell (HSC), which is both long-lived in vivo and capable of significant self-renewal. The latter capacity and the pluripotency of HSC is exploited to amplify the genetically manipulated cells into large numbers of progeny cell numbers of multiple blood lineages derived from the genetically altered cells in vivo. There is a long and successful experience in obtaining these stem cells from the bone marrow (BM) and peripheral and umbilical cord blood. There is extensive experience in the use of HSCs in the clinical setting for autologous and allogeneic transplantation, and there is the experience in the purification of these cells and limited knowledge of the requirements for ex vivo manipulation of the cells. In addition, the experience of HSC transplantation (HSCT) has defined a variety of genetic diseases in which the phenotype can be altered by the successful engraftment of normal allogeneic donor cells. Finally, the blood system is involved as a major dose-limiting organ in cancer therapies and both a target and an effector organ in immune reactions provide a large group of diseases that could theoretically be approached using gene transfer technology. As noted earlier, there are already many monogenic diseases of the blood extensively characterized with more being defined at the molecular level on a regular basis as whole-exome and whole-genome sequencing is being applied to rare disease phenotypes. In addition to HSC targets, another application of gene transfer technology exploits the experience in adoptive T-cell immunotherapy. In this application, T cells (and less well-developed to this point, other immune effector cells) are modified ex vivo to enhance potency and specificity. This application of gene transfer technology will not be reviewed here.

The field of gene therapy is rapidly evolving. Successes of "proof-of-principle" small trials have demonstrated the utility of the gene transfer approach in a growing number of patients but in a limited number of diseases leading to the first genetic therapies to be approved by regulatory agencies worldwide as therapeutic medicines. The technology itself is quickly evolving in response to new understandings of viruses, the regulation of gene expression, and improved gene-editing technologies. The application of gene transfer technology to HSC gene therapy has been made possible by the exploitation of viruses that have evolved the capacity to insert viral genomes efficiently and precisely into cellular chromosomes of infected cells. The field has taken >30 years to evolve to its current state of clinical application. Although this might be viewed as a slow pace, this time frame parallels the development of many other novel therapies. This developmental phase also reflects the complexities of the biologic systems involved and the caution required in moving forward in the face of serious adverse events seen in early safety trials. It is indeed an exciting time with respect to the clinical application of gene transfer technology in human diseases.

VECTOR SYSTEMS

The initial impetus to develop gene transfer for human studies derived from the exploitation of oncoretroviruses, mainly murine gamma (γ)-retroviruses, as vectors for gene delivery in the early 1980s. However, since these early studies, a multitude of virus vectors have been developed. All vector systems exploit the virus life cycle to increase the frequency and fidelity of the gene transfer. Although many vector systems have been developed, retrovirus and lentivirus vectors have become the most used platforms for human gene therapy trials involving HSC and T cell targets and this review will focus primarily on these vector systems (reviewed by Touw and Erkeland).[1] As noted, the majority of trials registered with the Recombinant DNA Advisory Committee (RAC) of the National Institutes of Health use retroviruses (both γ-retroviruses and lentiviruses) with non-integrating adenovirus vectors, adeno-associated virus, and nonvirus (liposomes and plasmids) systems making up the second and third largest groups. The latter is primarily focused on immune stimulation trials in cancer and have limited relevance to the use of HPSCs for the treatment of genetic blood diseases.

Retrovirus Vectors

The use of γ-retroviruses as gene transfer vectors takes advantage of the normal virus life cycle. In general, lentivirus vectors exploit a similar lifecycle as a vector system. The virus, a membrane-bound particle enclosing a dimer of genomic RNA, gag, and reverse transcriptase proteins, interacts with specific cell surface receptors on the target cell. After entry into the cytoplasm, the virus is uncoated, and the genomic messenger (m)RNA is reverse transcribed into DNA. Subsequent polymerase activity yields a double-stranded (DS) DNA provirus molecule. For γ-retroviruses, transport into the nucleus depends on the loss of the nuclear membrane, which accompanies cell division (see later discussion). Integration of the DS provirus in the chromosome is semi-random. The occurrence of insertional activation of oncogenes in several human trials and the subsequent scrutiny of insertion sites in HSC-derived progeny in both murine and human cells using deep sequencing methods have provided a more detailed understanding of subtle but biologically relevant preferences for insertions of these vectors (see later discussion). After being integrated, the provirus can give rise to mRNA leading to encoded protein products. Full-length (genomic) mRNA can also be used as the genomic nucleic acid in newly formed virus particles, which are budded nonlytically from the cell surface after assembly in the cytoplasm of the infected cell. The use of retroviruses for gene delivery depends on the capacity to replace viral genes with other heterologous gene sequences and to provide necessary viral proteins *in trans* in specialized cell lines, called *packaging cells*. The advanced generation of γ-retroviruses packaging cells appears to be capable of generating pure stocks of the recombinant virus without contaminating wild-type helper virus, an important safety consideration. Indeed, to date in human trials, there have been no reports of inadvertent generation of infectious viruses. Thus, the infection with replication-incompetent (i.e., helper-free) retrovirus vectors would be predicted to yield integration into the targeted cell population but no further spread of the virus in the body of the treated patient. The proteins provided *in trans* for γ-retroviruses are generally gag, reverse transcriptase, and envelope proteins, the latter defining the host range of infection. In summary, the advantages of retrovirus vectors include the high efficiency of stable transfer of intact DNA sequences, the broad range of host cells susceptible to infection by retroviruses, and for γ-retroviruses the ability to generate helper-free recombinant virus via stable packaging cell lines.

Despite these advantages, the application of retrovirus vectors for the treatment of human blood diseases in early trials was disappointing. In multiple studies, transduction of long-lived and transplantable HSCs was extremely low. In most studies, the frequency of circulating marked blood cells was too low to effect phenotypic correction of any disease, usually less than 0.1%. The biologic parameters contributing to the poor results in human trials are varied. The major impediments appear to include the low levels of viral receptors on the surface of human HSCs, reducing the efficiency of interaction of virus particles with these target cells, and the quiescent nature of the majority of HSC, which hinders the transport of the provirus into the nucleus and thus reduces the integration frequency. Practical issues, including the difficulty in obtaining high-titer viruses in large-scale preparations required for human trials, have also been noted.

These difficulties have led to various strategies and the development of entirely new vector systems, which seek to improve gene transfer methods in human HSCs. These strategies include attempts to increase virus–cell interactions or methods to enhance the chances of successful DNA integration. Different viral envelopes were used to pseudotype recombinant particles to more efficiently target CD34 cells. The use of various cell surface markers, such as CD34, to purify the target cell population can also increase the multiplicity of infection at a given virus titer and has been used in clinical transplantation protocols. Thus, the development of antibody-based enrichment of the $CD34^+$ HPSC compartment from human hematopoietic tissues using magnetic column purification provides a rapid, clinically applicable method to further enhance retroviral transduction by increasing the vector to target cell ratio. Methods to increase physical interactions between vector particles and target cells include co-localization on fibronectin and centrifugation methods. Where polycations such as polybrene had previously been used to enhance transduction frequencies by negating electrostatic charge repulsion between target cells and viral particles, the characterization of the recombinant CH296 fibronectin fragment (Retronectin™) as a matrix upon which one could co-localize HSCs and viral particles was a significant advance in the quest to improve $CD34^+$ transduction frequencies. More recently effective combinations of agents called "transduction enhancers" have been increasingly utilized in clinical trials. Other efforts to increase the chances of DNA integration have focused on attempts to increase the number of HSC that are undergoing cell division (primarily the use of cytokines that affect stem cell proliferation). The development of improved in vitro growth media formulations incorporating novel cytokine cocktails achieved the dual aim of promoting HSC division, which is required for transduction with γ-retroviral vectors and "activation" required for lentivirus vectors while minimizing stem cell loss via apoptosis or differentiation. Finally, the use of new virus systems that do not require nuclear membrane disruption (and, therefore, cell division) for entry of the provirus DNA into the nucleus, including primarily lentivirus vectors, but potentially also vectors based on foamy viruses, appears to be the most significant development in the field in the past decade. Lentivirus vectors will be discussed in more detail later.

In addition to advancing stem cell transduction methodology, additional work has focused on developing retroviral vectors that would express transgene cassettes at levels that would be high enough to elicit a therapeutic benefit and be resistant to gene silencing. Advances in vector design such as the optimization of long-terminal repeat (LTR) enhancer and promoter elements and viral leader sequences resulted in recombinant vectors that were able to mediate high-level transgene expression in both primitive and mature hematopoietic cells. As discussed in detail later, although these powerful promoter and enhancer elements provided a robust expression of transgenes, they appear also to be capable of long-range activation of endogenous regulatory sequences as a form of insertional mutagenesis that can have significant deleterious effects. Taken together, these technological advances served as the platform for the first successful gene therapy trial in humans.

The use of pharmacologic in vivo selection in combination with gene transfer, both in the setting of cancer trials and in genetic diseases, remains a potentially important method to enhance the reconstitution of human recipients with gene-modified blood cells but has not yet gained widespread usage. General considerations include the need for a particular drug to effect damage to BM stem or progenitor cells. A gene's or genes' encoding resistance to this agent would need to be identified and resistance in vivo to the agent would need to be demonstrated after overexpression of this gene in BM cells.

For applications in cancer therapies, dose intensification of drugs used within chemotherapeutic regimens should improve antitumor efficacy. Work is ongoing to use the transgenic expression of O^6-methylguanine methyltransferase (MGMT) which generates resistance to bis-chloroethylnitrosourea (BCNU), temazolamide (TMZ) and 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea (CCNU) and cytidine deaminase which generates resistance to cytosine arabinoside, gemcitabine, decitobine, and azacytodine for applications in cancer. For non-cancer applications (for the co-selection of a non-selectable therapeutic gene in a genetic disease application), the mutagenic potential of the chemotherapy agent must be considered as a risk in relation to the overall benefit of the gene therapy procedure. Several chemoresistance genes and chemotherapy drug combinations are currently under investigation for this application and encouraging preclinical studies in model systems, including murine and canine studies, have led to a limited number of early-phase human studies in cancer patients.

Lentivirus Vectors

One of the key advances in the gene therapy field in the past decade has been the development of recombinant vectors based on lentiviruses, including the human immunodeficiency virus (HIV). These vectors were originally developed after the observation that targets of HIV included more differentiated cells, such as macrophages, that are often also post-mitotic, suggesting this group of retroviruses has evolved a method of circumventing the block in infection of γ-retroviruses seen in non-dividing cells. Investigators demonstrated that lentivirus vectors derived from HIV were capable of infecting non-dividing neurons after direct injection into the brain. Subsequently, Naldini and colleagues showed efficient infection of growth-arrested cells. As with γ-retroviruses, lentivirus vectors use key viral gene products *in trans* to generate replication-defective infectious particles carrying the transgene of interest. To date, most lentivirus vectors use vesicular stomatitis virus as an envelope sequence, which provides a very broad range of target cells susceptible to lentivirus vector transduction. In the case of lentivirus vectors, viral gag and pol, as well as tat and rev proteins, expression are required *in trans* for efficient virus production along with the envelope proteins. These proteins are usually supplied from separate plasmids, and recombinant lentivirus production is today generally created using the "four plasmid" systems encompassing all the necessary viral proteins on three plasmids and the transfer vector sequences of the fourth plasmid. In addition to *gag* and *pol*, the transfer vector contains all the virus regulatory sequences required *in cis* for packaging an infectious particle, including the *psi* packaging sequence, integrase, and reverse transcriptase. In almost all clinical applications to date, the recombinant lentivirus vector is generated as a transient supernatant from a population of transfected producer cells rather than a clone and each large-scale batch of viruses has variable yields. Thus, the generation of high-titer recombinant virus is more complicated than γ-retroviruses and remains a significant issue for large-scale, clinical-grade production for use in human trials.

To reduce the chances of the generation of replication-competent retroviruses (RCRs), a major safety concern with HIV, most of the nonessential viral sequences have been removed from currently utilized vectors. This included *viv, vpu, vpr*, and *nef* genes and subsequently *tat*, an important regulator of viral transcription. Recombinant vectors generated without these sequences were demonstrated to efficiently infect a variety of cells. RCR testing is based on sensitive assays to detect a gag protein by p24 immunoassays or polymerase chain reaction. In addition, lentivirus vectors have traditionally been produced using the "self-inactivating design" (SIN) for added safety because of the reduced risk of recombination with and subsequent mobilization of endogenous HIV viruses. The transfer vector thus contains a deletion of the 5′ LTR U3 region and are devoid of viral enhancer and promoter sequences. During reverse transcription, the 5′ LTR is replicated, and the integrated provirus is thus devoid of both 5′ and 3′ enhancers. In SIN constructs, the transgene of interest is thus expressed from an internal promoter that can be chosen with varying strengths or lineage specificities. This added safety feature ultimately has proven important in reducing the risk of insertional mutagenesis (see later) by which integration near cellular genes are inadvertently activated by the LTR enhancer sequences of vectors.

Lentivirus vectors were originally developed for use in a wide range of tissues in which cells are largely non-dividing. Early work focused on the brain, retinal cells, liver, pancreatic islets, airway epithelium, and muscle. However, it was subsequently appreciated that the requirement of stimulating HSCs into division with various cytokines to effect efficient transduction with γ-retrovirus vectors may have negative effects on engraftment or that a large fraction of HSCs remain quiescent and, therefore, resistant to transduction during clinical transduction protocols. After several groups reported successful transduction of primitive HSC populations in protocols in which these cells remained resistant to transduction by γ-retroviruses, the adoption of lentivirus vectors has now included multiple human trials with encouraging results. One of the earliest trials to utilize lentivirus vectors was in childhood cerebral adrenoleukodystrophy (CCALD)[2] in which long-term "marking" in the myeloid compartment appears to be 10% to 20%, a level that is about 100-fold higher than the marking in the myeloid compartment seen in previous trials in immunodeficiency conditions that used γ-retrovirus vectors. In addition to the safety advantage of SIN vector design used in all lentivirus vectors, there is an additional theoretical advantage of the preference of lentiviruses for integration away from transcription start sites (TSS) of genes in contrast to γ-retroviruses. However, the recent experience with a lentivirus vector used in a single patient with thalassemia[3] in which abnormal splicing resulted in clonal expansion in the erythroid compartment, suggests that insertion within genes including intronic and non-coding regions of genes may also have potential adverse effects on endogenous sequences. These trials are described in more detail later. Thus, the long-term safety of lentiviruses in human trials remains to be determined, and important aspects of insertional mutagenesis are described in more detail later.

EXPERIENCE IN HEMATOLOGIC CLINICAL TRIALS TO DATE

X-Linked Severe Combined Immunodeficiency

Severe combined immunodeficiency (SCID) comprises a number of rare monogenic diseases with the common feature of a block in T-cell differentiation and impaired B-cell and natural killer (NK) cell immunity. Studies of the pattern of inheritance, immune function, and genotypes have led to the identification of at least 18 distinct SCID conditions with the number increasing as genomic sequencing identifies mutations in additional immunodeficiency phenotypes. The most common variant of SCID results from the deficiency in the expression or function of the common cytokine receptor γ chain, which is shared by the receptors for interleukin (IL)-2, IL-4, IL-7, IL-9, IL-15, and IL-21. This condition is inherited in a sex-linked fashion (X-linked SCID or SCID-X1) and accounts for ~30% of all SCID cases. SCID-X1 is characterized by abnormal development or function of T, B, and NK cells, although B cells are usually present in humans (so-called T-minus, B-plus SCID). Survival depends on the reconstitution of T-cell development and function by allogeneic BM transplantation (BMT). If a genotypically matched family donor is available, HSCT confers a greater than 80% chance of long-term survival. The absence of T and NK cells in the patient allows for the engraftment of donor cells without preparative chemotherapy conditioning; thus, this is the treatment of choice with minimal toxicity. When a genotypically matched family member is not available, haploidentical donors (e.g., a parent) or closely matched unrelated donors are used, with varying preference from center to center, and a survival rate of 64% to 78% has been reported. These inferior outcomes may be attributed to the increased risk of graft rejection or graft-versus-host disease (GVHD), as well as the effects of T-cell depletion, immune suppression causing slower immune reconstitution, or conditioning with an increased risk of infection. Haploidentical transplants rigorously depleted of T cells, similar to genotypically related transplants, are performed in some institutions without preparative chemotherapy conditioning; however, B-cell reconstitution is poor, and the majority of patients require intravenous immunoglobulin (IVIG) replacement for life. Interestingly, spontaneous partial correction of severe T-cell immunodeficiencies, including SCID, has previously been reported, suggesting a selective advantage of wild-type T cells over defective T cells.

Multiple independent gene therapy trials aimed at correcting the immunologic defect of SCID-X1 patients who lack a genotypically matched BM donor have been reported.[4] In the initially reported trials, done in Paris and London, a total of 20 patients have been treated.[5,6] Despite minor technical differences in the two protocols, the basic design of both gene therapy trials is quite similar: The complete coding region of the human γ chain was cloned into a "first-generation" γ-retroviral vector regulated by the murine leukemia virus (MLV) LTR sequences, which was used to infect BM-derived CD34$^+$ cells in vitro. Results in both trials have been extremely encouraging.

In the French trial, 10 children younger than the age of 1 year were enrolled between 1999 and 2002. Nine of 10 infants developed normal numbers of T and NK cells, with good immune function. In seven of the nine patients who developed T cells, T-cell counts reached normal levels within three months and have remained normal at the time of the last published follow-up. Protective levels of antibodies, including antibody production after immunization, were achieved, and the prophylactic administration of IVIG was discontinued. At almost >10 years after gene therapy, these patients continued to retain a functional immune system, enabling them to live normally.

However, serious adverse events related to gene therapy have been reported in five patients in the French trial, occurring up to 15 years after gene therapy and in one patient in the British trial. In these patients, untoward effects of viral integration into the genome resulted in T-cell leukemia, leading to the death of one of the affected patients. Much research has subsequently been directed at elucidating the mechanism responsible for these adverse events. Retroviral integration in the proximity of proto-oncogenes, particularly the *LIM domain only 2* (*LMO2*) promoter, was involved in leukemogenesis in three French patients and one British patient. Integration of the unaltered γ chain–encoding viral vector on chromosome 11q13, near the first exon of the *LMO2* gene, led to the unregulated transcription of LMO2, giving rise to a T-cell acute lymphoblastic leukemia (T-ALL)–like lymphoproliferation in the initial two patients. In the patient in the British trial, the integration of the vector 35 kb upstream of the *LMO2* locus cooperated with secondary genetic aberrations, including a gain of function mutation of NOTCH1, a deletion at the CDKN2A tumor suppressor gene locus, and translocation of the T-cell receptor β region, to give rise to T-ALL. LMO2 is a master regulator of human hematopoiesis that is involved in stem cell growth and is not normally expressed in T cells. However, LMO2 activation has been implicated in some cases of human T-cell leukemia. In addition, LMO2 transgenic mice have been shown to develop T-ALL within 10 months. It is increasingly clear that retroviral vectors may "turn on" cellular proto-oncogenes adjacent to their integration site in the genome. The strong promoter or enhancer activity of the retroviral LTR element shows a propensity to the upregulation of genes neighboring the integration site. Multiple studies now indicate that γ-retroviral vectors, such as the vectors used in the two SCID-X1 trials, preferentially integrate into the 5′ end of genes near the TSS. In addition, γ-retroviral vectors have been shown to integrate into or near a number of proto-oncogenes that are actively expressed in human CD34$^+$ cells. When human CD34$^+$ cells were transduced with retroviral vectors ex vivo, 21% of retroviral integrations occurred at recurrent insertion sites ("hot spots"), which were highly enriched for proto-oncogenes and growth-controlling genes. A series of papers investigating the vector integration sites in both SCID-X1 trials and a trial treating Adenosine Deaminase (ADA) Deficiency SCID trial (see below) observed a greater-than-random frequency of vector integrations near the TSS of genes that are active in HSCs. Interestingly, in the SCID-X1 trial, a skewing of vector integration site distribution in vivo was noted. Compared with retroviral integration sites (RIS) recovered from transduced CD34$^+$ cells, RIS recovered from T cells in vivo 9 to 30 months after transplantation showed an overrepresentation of RIS within or near genes encoding proteins with kinase activity, transferase activity, or proteins involved in phosphorous metabolism. This skewing of RIS in vivo suggests a selection of T cells as a result of viral integration in certain growth- and survival-promoting genes. A subsequent trial in X-SCID utilizing a SIN γ-retrovirus design (NCT01129544) reports follow-up on nine patients, although the trial has now closed for accruing patients.[4] The virus design is noteworthy in that it is more directly comparable to a lentivirus since the viral enhancer elements are deleted and the expression of the IL-2 γ chain is from an "internally positioned" cellular promoter. The initial results reported efficacy similar to the previous SCID-X1 trials, no leukemia and integration analysis that appears safer than those seen in the previous two trials. In the eight evaluable patients treated in this trial, six demonstrated correction of T-cell reconstitution. One patient died prior to full engraftment of gene-modified cells of pre-existing viral infection that did not resolve after gene therapy. The two failures correlated with lower VCN in the transduced product as a result of inadequate gene transfer. This study is particularly noteworthy as the only human study in which a γ-retrovirus vector deleted of enhancer elements has been utilized. It thus provides a platform for more direct comparison with previous γ-retrovirus and lentivirus trials with respect to safety and efficacy. More recently, a trial using similar cis-regulatory elements driving the gamma chain cDNA in a lentivirus vector has been reported, which includes the successful reconstitution of the B-cell compartment after including conditioning with busulfan.[7]

In summary, thus far, six of 20 patients treated with gene therapy for SCID-X1 have encountered a life-threatening severe adverse event, thought to be triggered by retroviral activation of LMO2 in four patients. Four patients were salvaged with chemotherapy, and one patient succumbed to the disease after an unsuccessful allogeneic BMT. At this point, the use of MLV-based retroviral vectors with LTR promoter enhancer elements intact is viewed as contraindicated in this disease by most investigators in the field. The continued development of safety-enhanced vectors and the validation of these vectors in clinically relevant systems have emerged as a major priority in the field, and an international trial has recently been reported using a γ-retrovirus that is deleted of LTR enhancer elements. Transgene expression is mediated by a weak cellular promoter in this vector. Data suggest that early efficacy is maintained despite lower expression of the cγ chain and that the deletion of the γ-retrovirus enhancer is a key to improved safety.[4]

Adenosine Deaminase Deficiency

ADA is a housekeeping enzyme of the purine metabolic pathway that is expressed in all tissues of the body. Deficiency of this enzyme leads to a buildup of toxic metabolites with detrimental systemic effects, including neurodevelopmental deficiencies, sensorineuronal deafness, and skeletal abnormalities. Importantly, ADA deficiency causes abnormal T-, B-, and NK-cell development, resulting in the SCID phenotype. As is the case with the more common SCID-X1, untreated patients generally succumb to severe opportunistic infections in the first year of life. Treatment strategies used to manage affected patients include allogeneic HSCT; enzyme replacement therapy; and more recently, gene therapy. Allogeneic HSCT from a human leukocyte antigen (HLA)–matched family donor offers good immunologic and biochemical correction with reasonable survival. However, outcomes after mismatched and haploidentical transplants are less impressive. Likewise, the exogenous replacement of ADA, administered in a polyethylene glycol (PEG) conjugate by intramuscular injection on a weekly or twice-weekly schedule, results in systemic detoxification and immune reconstitution. In the long term, however, about half of the patients receiving PEG-ADA replacement continue to require IVIG infusions, and some patients show a decline in T-cell numbers over time.

A number of gene therapy trials for ADA deficiency were initiated in the early 1990s, targeting retroviral gene transfer into various cell types, including peripheral blood lymphocytes, umbilical cord blood, BM, and CD34$^+$ selected stem cells. These early studies failed to produce clear efficacy. By contrast, later studies introduced key modifications to the gene therapy protocol, including the use of a reduced-intensity myelosuppressive conditioning regimen and the withdrawal of concurrent PEG-ADA replacement. The Milan-based group of Aiuti and colleagues reported on their initial experience with 10 children. Patients were conditioned with 4 mg/kg of busulfan before the infusion of transduced cells. The mean age at the time of gene therapy was 2.2 years. All children on this trial were reported as healthy and thriving, with the longest published follow-up time more than 64 months. Gene therapy resulted in a substantial increase in lymphocyte counts and normalization of T-cell function. An update on this trial,[8] published in abstract form, reports that 18 patients have been treated and are alive and, of these, 15 do not require replacement enzyme treatment (reviewed in 2017 by Ferrua and Auiti).[9]

Similarly, four patients have been treated in London.[10] One patient that has been reported in detail had been treated with PEG-ADA for 3 years but showed a gradual decline in T-cell numbers despite effective metabolic correction. Because a matched BM donor was not available, the patient was enrolled on the ADA-SCID gene therapy trial. The PEG-ADA replacement was stopped one month before gene therapy, and the patient was conditioned with a single dose of 140 mg/m^2 of melphalan before the infusion of the transduced BM CD34$^+$ cells. At the time of the last published follow-up, the patient was 2 years from gene therapy, clinically well, and off prophylactic antibiotic therapy. An increase in T-cell numbers and normalization of the proliferative response have been noted. Importantly, no adverse events have occurred thus far in the patients treated for ADA-SCID at these two centers.

Aiuti and colleagues recently published a comprehensive genome-wide analysis of RIS of five patients treated in Milan. This paper analyzed the RIS patterns in CD34$^+$ cells before infusion as well as RIS in vivo, up to 47 months after gene therapy. As anticipated, a nonrandom proviral integration pattern, favoring TSS and gene dense regions, was observed in the pretransplant cells. RIS observed in vivo in T cells were additionally enriched for TSS, suggesting the occurrence of in vivo selection. More recently, Aiuti and colleagues[11] have demonstrated that cellular genes in the proximity of the proviral integration site are subject to moderate dysregulation in gene-modified T-cell clones isolated from patients. However, in contrast to the SCID-X1 trial, no in vivo skewing toward RIS in genes affecting survival, cell cycling, signal transduction, or proliferation were observed, making a clonal dominance effect appear less likely. Interestingly, only one *RIS* was detected at the myelodysplastic syndrome (MDS)-EVI1 locus and became undetectable at later time points. This is in contrast to the clonal dominance of *MDS-EVI1* integration sites observed in the X-linked Chronic Granulomatous Disease (CGD) trial (see below). Additionally, an overrepresentation of RIS was noted in the proximity of the *CCND2* and *LMO2* gene with a total of five of 523 RIS recovered in vivo. Notably, the *CCND2* insertions were detected only in the first 2 years of follow-up and not subsequently. *LMO2* insertions were also overrepresented in the pretransplant CD34$^+$ samples, highlighting the fact that the *LMO2* gene is a hot spot for retroviral integration in human CD34$^+$ cells. The lack of in vivo expansion of clones carrying LMO2 RIS indicates that this integration site may not be sufficient to mediate clonal dominance and leukemic transformation. Rather, additional cooperating mutations or insertions are required for malignant transformation. The γ-retrovirus vector (Strimvelis™) has been approved by the European Medicines Agency (EMA). However, recent leukemia has been reported in a patient treated with this vector attributable to insertional mutagenesis. A multi-center trial utilizing a lentivirus platform that has completed accrual (NCT01279720) with encouraging results is currently being reported.[12]

CHRONIC GRANULOMATOUS DISEASE

CGD is an inherited disorder of phagocyte dysfunction characterized by often life-threatening invasive fungal and bacterial infections and by granuloma formation in vital organs. CGD results from a mutation in one of four subunits of the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase of phagocytes. The inability to form microbiocidal oxygen species renders the phagocytes unable to fight invasive infections. Almost 70% of CGD cases result from defects in the X-linked gene encoding gp91^{phox} (X-CGD). With conventional therapy, including lifelong antimicrobial prophylaxis and interferon-γ therapy, the yearly mortality rate of X-CGD remains at 5%. HSC transplantation is curative for patients with a perfectly matched sibling donor but remains risky in patients with active infections. Unrelated donor transplantations are not routinely recommended. Thus, the development of a gene therapy approach that uses autologous HSC provides an important therapeutic advance for this patient group. In previous clinical gene therapy trials conducted without myeloreductive conditioning, the engraftment level of gene-modified cells remained low.

In 2002, the German group of Grez and colleagues in Frankfurt, Germany, initiated a gene therapy trial of X-CGD. The initial patients received a mild immunosuppressive preparative regimen and failed to engraft significant numbers of gene-modified cells. However, 2 years later, low-dose busulfan—modeled on the successful gene therapy trial for ADA-SCID—was incorporated into the preparative regimen, and additional patients were treated. This group of patients has been followed with unprecedented sophistication by the prospective monitoring of integration sites that mark each hematopoietic cell before transplantation and then allows the tracking of these cells in vivo. The initial two patients treated were 26 and 25 years old. Both subjects carried the diagnosis of X-CGD and had failed to clear invasive infections, including a *Staphylococcus aureus* liver abscess and pulmonary aspergillosis with medical treatment. Thus, autologous peripheral blood CD34$^+$ cells were mobilized with the granulocyte colony-stimulating factor (G-CSF) and collected. Gene transfer was performed using a gammaretroviral vector SF71gp91^{phox}. This vector, containing the spleen focus-forming virus LTR elements (in contrast to the Moloney MLV LTR in the two SCID trials) was chosen for its ability to achieve high expression levels in transduced HSCs. The in vitro transduction rates in the two patients were 45% and 39.5%, respectively, with a proviral copy number of 2.6 and 1.5 per transduced cell. Proviral integration occurred preferentially in gene-coding regions (47% to 52%) and was highly skewed toward the 5-kb sequence surrounding TSS. Moreover, the clonal distribution pattern was not stable over time. Rather, starting five months after therapy, a less diverse integration pattern emerged, indicating the appearance of dominant clones.

Clinically, following a period of cytopenia after the conditioning and cell infusion, the initial engraftment rates detected in the peripheral blood were 12% to 13%. Significant improvement in the previously refractory infections was noted 50 to 60 days after therapy. A gradual increase in the number of gene-corrected cells up to 50% to 60% of all peripheral blood cells was observed, starting around day 150 after transplant. This coincided with increased oxidase activity and occurred in the absence of altered blood counts. These events were accompanied by a selective outgrowth of progenitors carrying vector insertions that activated one of three oncogenes, PR domain containing 16 (*PRDM16), SETBP1*, and most notably *MDS-EVI1*. Although all three genes are well-known cancer-associated genes, most clonal outgrowths were exhausted after a few months with the exception of *MDS-EVI1*, which increased to 67% to 90% in both patients approximately 1 year after cell infusion. Of note, the dominant *MDS-EVI1* clones initially did not transgress the boundaries of the normal myeloid pool because these cells remained cytokine-dependent in vitro and failed to engraft in immunocompromised mice, suggesting their benign nature. Thus, the expansion of gp91^{phox+} cells, although clearly providing therapeutic benefit during the initial phase, was viewed with mixed feelings by the investigators and the general gene therapy community.

A follow-up on these two study patients has been provided.[13,14] Indeed, although gene-marking remained high in both patients, downregulation of gene expression was noted as a result of CpG methylation in the viral LTR promoter. As a consequence, gp91^{phox}

expression was suppressed, but the capacity of the LTR encoded enhancer to transactivate nearby genes remained intact. One patient died 2.5 years after therapy of severe sepsis. The second patient developed monosomy 7 and MDS and died after an unsuccessful unrelated donor BMT.[13] Of note, the *EVI1* locus has previously been identified as a common target of retroviral oncogenesis. EVI1, which is not detected in normal hematopoietic cells, has been associated with myeloid leukemia and MDS. The constitutive overexpression of Evi1 in mouse BM cells has been shown to induce MDS in mice and data from the CGD trial suggest that dysregulated expression is associated with genomic instability, presumably contributing to the acquisition of additional somatic mutations. Despite these molecular events, the infusion of gene-corrected CD34$^+$ cells was highly effective with regard to clearing refractory pyogenic infections, raising the possibility of using gene therapy to bridge patients with refractory pyogenic infections into eligibility for allogeneic HSCT. A multi-institutional international trial has recently opened in which the GP91^{phox} gene is expressed in a lentivirus backbone via a chimeric myeloid internal promoter (NCT01855685). The initial report of results of this trial demonstrated 6 of 9 treated patients has 16% to 46% oxidase-positive neutrophils at 12 months post-treatment. No CGD-related infections were seen in the surviving patients.[15]

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome (WAS) is an X-linked immunodeficiency caused by inactivating mutations in the WAS protein (WASP). WASP plays a regulatory role in cell signaling and cytoskeletal reorganization in hematopoietic cells. The disease is fatal and characterized by SCID, thrombocytopenia, elevated frequency of tumor formation, eczema, and other autoimmune manifestations. The only currently available curative therapy for WAS is a BM transplant, but as with the other primary immunodeficiencies, the availability of suitably matched donors is limiting. A clinical trial for the genetic correction of WAS via retroviral delivery of the WASP cDNA into autologous CD34$^+$ cells was recently reported.[16] A combination of a relatively high cell dose (7 to 8 × 10^6 CD34$^+$/kg body weight) and good transduction efficiency led to gene marking across both myeloid and lymphoid lineages. A marked clinical benefit from gene therapy has been reported in one of the patients.[16] Of particular note is the fact that the architecture of the vector backbone used in this trial is similar to that used in both the CGD and the SCID trials described earlier. That is, the gammaretroviral vector has an intact LTR that contains the enhancer and promoter from the spleen focus forming virus.[17] Leukemias from insertional mutagenesis in seven of the ten patients in this trial have been described.[18] Thus, a common molecular etiology in this trial strongly suggests that the initial vector design (intact strong viral LTRs containing enhancer elements that can transactivate promoters over long distances) are unsafe. In addition, the occurrence of T-cell leukemia in a disease other than SCID weakens the argument that the leukemias in X-SCID was related either to the transgene or to some unknown disease-specific characteristic. In any regard, use of the "first–generation" MLV backbone in human trials may now be ended. Several more recent clinical trials have utilized a SIN lentivirus vector for the treatment of WAS (NCT02333760, NCT01410825, NCT01347346). These trials utilize the same vector backbone. In a total of 10 patients studied, nine were reported alive and showed clinical benefit with reduced autoimmunity, including improvement in eczema and reduced platelet transfusion dependence with no serious bleeding. One subject died from a pre-existing viral infection that did not resolve after gene therapy. One study noted that the degree of myeloid engraftment and platelet reconstitution in this disease treatment correlated with the dosage of gene-corrected cells.

Childhood Cerebral X-Linked Adrenoleukodystrophy

Childhood cerebral X-linked CCALD is a fatal neurodegenerative disease that results from progressive neural demyelination within the brain. The defective gene that is responsible for the phenotype, adenosine triphosphate–binding cassette D1 (*ABCD1*), encodes a transmembrane transport protein that is responsible for the shuttling of fatty acids into peroxisomes, where they are subsequently degraded. ALD is characterized by an accumulation of very long chain fatty acids, although the exact pathophysiology of the disease is unknown. Cerebral demyelination is associated with inflammation evident on gadolinium magnetic resonance imaging studies. Most patients progress from no symptoms to a vegetative state and death within 5 years of diagnosis. Allogeneic BM transplant has been found to be therapeutic for cerebral demyelination, presumably because of the infiltration of donor-derived microglia cells into the brain. However, because of the very rapidly progressive nature of the demyelination and the time required to generate mature microglia from transplanted HSCs, BM transplant is most effective when administered as soon as possible after the development of demyelination evident by imaging methods. In cases in which CCALD is successfully treated with HSCT, continued progression of the disease occurs for 18 months to 2 years before disease arrest. Myelin inflammation resolves, but lost neurologic function is not regained in successfully treated patients. Because of the time constraints imposed upon finding a suitable HLA-matched donor and the occurrence of GVHD, the genetic correction of autologous BM CD34$^+$ cells is an attractive experimental therapeutic option.

A phase 1 gene therapy trial using a recombinant HIV-1 based lentiviral vector to deliver the ABCD1 cDNA into CD34$^+$ cells has been reported from Paris.[2] This trial is particularly noteworthy in that it is the first trial to report reconstitution of BM cells that have been transduced with a recombinant lentiviral vector. Molecular characterization of lentiviral integration sites in engrafting cells indicated that the reconstitution was polyclonal, but detailed analysis of genomic loci targeted by this vector has yet to be reported. A multisite, biotechnology-sponsored phase 2/3 registration trial accruing patients in several countries using a similar lentivirus vector in this disease has been completed and initial results reported showing that 15 of 17 boys treated were alive and free from major functional disabilities with minimal clinical symptoms.[19] This study has accrued 32 patients and recently closed for additional enrollment, but final results have not been reported. One ongoing trial is accruing additional patients utilizing the same vector but with a modified conditioning regimen (NCT03852498).

β-Thalassemia

Thalassemia results from mutations that attenuate the expression of either the α or β globin chains that compromise hemoglobin synthesis and thus causes ineffective erythropoiesis. Because adult hemoglobin consists of a tetramer of two α and two β chains, inherited mutations at the β globin locus cause a mismatch in the ratio of these two chains, thus preventing the correct assembly of the hemoglobin molecule. Clinically, this may result in transfusion-dependent anemia, which in turn can promote the serious side effect of iron overload. In general, disease severity correlates with the degree to which inactivation mutations inhibit β-globin expression. However, other genetic loci can modulate the disease phenotype, for example, by inducing adult expression of the fetal γ-globin gene, which can be efficiently incorporated into functional hemoglobin in place of the β-globin chain. For instance, several groups have recently demonstrated that the transcription factor BCL11A plays a major role in regulating the expression of fetal hemoglobin and a key to switching γ globin off and adult β-globin expression on during the transition from fetal to adult life and the BCL11A gene has become a therapeutic target for the treatment of β-thalassemia.[20] Gene therapy of β-thalassemia is complicated by the requirement for an exact stoichiometry of α- and β-globin chains to facilitate efficient assembly of hemoglobin. Thus, an effective gene therapy vector must be able to facilitate high-level expression of β-globin in the range of that mediated by the normal endogenous gene in an erythroid-specific context.

Patients treated in an initial clinical trial that used a lentiviral vector for the correction of β-thalassemia have been reported.[3] The lentiviral vector used in the trials mentioned above comprises a SIN configuration with elements from the β-globin LCR driving expression of the β-globin cDNA that has been mutated to enhance β-globin chain stability. An interim report on the findings of the clinical trial describes that, in 2007, a single patient with severe transfusion-dependent β-thalassemia major received $CD34^+$ cells transduced with the lentiviral vector described earlier.[3] There was a clear demonstration of clinical efficacy because the patient has been transfusion independent for 15 months. Of note, posttransplant molecular analysis revealed a mild clonal skewing comprising less than 5% of peripheral blood cells. The clone, which harbors a proviral integration within the high-mobility group A2 proteins (*HMGA2*) gene locus, is reported to be stable. Insertion of the provirus into this locus resulted in the production of a 3′ truncated mRNA resulting from the introduction of a cryptic splice acceptor, present in the vector insulator element, into intron 3 of the gene. This truncated mRNA, comprising exons 1 through 3, was expressed at elevated levels because of a loss of negative posttranscriptional regulation by Let-7 miRNAs because the miRNA target sequence in exon 5 was lost. *HMGA2* has been found to be mutated in chromosomal translocations primarily in benign tumors and less often in malignant tumors. Although the clinical implications of this clonal outgrowth are unclear, this event clearly demonstrates that lentiviral vectors can contribute to insertional mutagenesis albeit, in this case, via modulation of posttranscriptional regulation of gene expression. Indeed, the propensity to insert in coding sequences may lead to an abundance of abnormal mRNA splicing variants.

More recently, data from a multicenter gene therapy trial using a lentivirus vector to treat β-thalassemia has been reported.[21] In 12 of 13 non β^0/β^0 (less severe phenotype) patients treated, red cell transfusions were able to be discontinued with hemoglobin levels increasing to 8.2 to 13.7 gm/dL. In 9 β^0/β^0 (severe phenotype) patients treated the annualized red cell transfusion burden decreased 73% and in 3/9 patients, it was reported that red cell transfusions were discontinued altogether.

Sickle Cell Disease

The treatment of sickle cell disease by gene therapy approaches has utilized multiple approaches. Several trials use lentivirus vectors to express either sickling-resistant β-globin protein, γ-globin, or to increase expression of protective fetal hemoglobin by reversing the so-called fetal to adult globin switch based on recent data showing the "cure" of humanized sickle mice[22] by genetic deletion of BCL11A. The largest study has reported 19 patients in an ongoing phase 1/2 trial (NCT 02140554) treated with the $\beta^{A\text{-}T87Q}$ Lentiglobin™ vector using mobilized peripheral blood CD34 cells.[23] In this study, 13 patients stopped all red cell transfusions with a median sickle hemoglobin (HbS) reduced to <50% and correction of anemia with median Hb levels of 11.5 gm/dL. Eight patients who had a median annualized incidence of 5.3 vasoocclusive or acute syndrome episodes prior to treatment had no episodes after genetic therapy. While these results are encouraging, two patients treated in an earlier version of this trial have developed acute myeloid leukemia (AML). The etiology of these leukemias is unclear, but at least in one case it was not associated with insertional mutagenesis.[24]

An alternative approach to treating SCD is to silence the BCL11A gene. As noted above, BCL11A is a major repressor of fetal globin expression. The silencing of BCL11A has been accomplished either by expressing an shRNA against this transcription factor embedded in a microRNA or by gene-edited deletion of the *BCL11A* enhancer gene in HSCs and preliminary results of both approaches have been reported and show promising results.[25,26] In both reported trials, significant induction of fetal hemoglobin was accompanied by mitigation of anemia and vaso-occlusive events with good safety profiles, although follow-up is relatively short. These trials represent important extensions of the technology from very rare diseases to a disease with a much larger patient population.

INSERTIONAL MUTAGENESIS

From an early stage in the development of retroviral vectors for gene therapy applications, there has been a concern that recombinant vectors could elicit cellular transformation by altering the expression of either cellular proto-oncogenes or tumor suppressor genes that are proximal to the genomic integration site. This phenomenon, referred to as insertional mutagenesis, was characterized as a property of wild-type γ-retroviruses. Having greatly reduced the likelihood that retroviral gene therapy vectors could generate a replication-competent virus, the risk of a recombinant vector being able to transform a cell via insertional mutagenesis was initially perceived by many investigators to be very low. The lack of efficacy in preclinical models using human hematopoietic stem and progenitor ($CD34^+$) cells also shifted emphasis away from the risks of insertional mutagenesis. However, soon after the publication detailing the efficacy of the Paris-based SCID-X1 trial, work emerged from the group of Baum and colleagues that would reestablish the importance of insertional mutagenesis as a significant risk factor in the retroviral-mediated genetic correction of hematopoietic cells and that ultimately predicted the appearance of leukemia in the SCID (both SCID-X1 and ADA-SCID), CGD, and WAS gene therapy trials described earlier. Baum demonstrated for the first time that a replication-incompetent retroviral vector backbone designed for gene therapy applications could cause cellular transformation via insertional mutagenesis in the context of a transplant model of transduced murine HSCs. In this, and a subsequent study, it was found that a single retroviral insertion in the vicinity of the ecotropic viral integration site 1 (*Evi1*) gene or the related *PRDM16* gene resulted in their overexpression likely because of the influence of the LTR viral enhancer element and was sufficient to initiate a cascade of events resulting in a leukemic transformation in vivo. Furthermore, a high copy number infection of murine BM with recombinant retroviral vectors was able to facilitate combinatorial hits which caused leukemogenesis. The pattern of cellular genes that combine to promote cellular transformation demonstrated a significant overlap with those that are deregulated in experiments that used replication-competent retrovirus vectors to provoke the development of leukemia. Although murine HSCs likely represent a more readily transformed target than their human counterparts, these studies formally established the mutagenic potential of recombinant retroviral vectors intended for gene therapy applications.[27]

Thus far, leukemias associated with replication-incompetent retrovirus vectors are associated with insertional activation of known proto-oncogenes by a viral promoter and enhancer sequences (reviewed by Kohn et al.[28]).

Wild-type and recombinant retroviral vectors (including α, γ, spuma, and lenti) integrate into the host genome in a semi-random manner and demonstrate insertion site biases that are dependent on the accessibility of the insertion site in the target cell and variations in the viral integrase enzyme that depend on the retroviral genus. γ-retroviruses such as MLV have been shown to exert a clear preference for integration in the region immediately surrounding the TSS of actively transcribed genes. Although lentiviral vectors also demonstrate a preference to integrate within the loci of actively transcribed genes, their integration profile favors sites that are downstream of the TSS within the body of the primary transcript.

As noted earlier, other related retroviral vector systems have also been shown to have an integration pattern that is distinct from gammaretroviral vectors and, as such, may represent a safer vector configuration. Recombinant foamy virus vectors do not preferentially integrate within genes, and their integration pattern does not significantly correlate with actively transcribed genes. Likewise, avian sarcoma leukosis (alpharetrovirus) vectors do not favor gene-rich regions or TSS as preferred integration sites. However, these novel vectors systems have not been as well characterized as gammaretroviral or lentiviral vectors with regards to safety and efficacy and have not yet been translated to clinical use in the near future.

RECENT MODIFICATIONS OF VECTOR SYSTEMS BASED ON CLINICAL EXPERIENCE

New Cell Targets in Genetic Engineering

Despite recent advances in improving ex vivo manipulation of HSC for the purpose of gene transfer, an ongoing limitation of this technology is the loss of engraftment potential of manipulated cells. This is dramatically emphasized in genetic diseases such as Fanconi anemia, in which the disease process itself leads to a marked reduction in HSC targets and, in addition, HSCs, which appear to have increased susceptibility to in vitro stress. An exciting area of recent research advances that may in the future address this issue and also allow prescreening at the molecular level of insertions to determine safety is the use of embryonic stem (ES) or *induced pluripotent stem* (iPS, see next paragraph) cells. These cells offer exciting possibilities for studying mechanisms of pluripotency; establishing models for disease-specific investigations; and enabling future applications in genetic and cellular therapies, including tissue engineering for regenerative medicine. ES cells can be propagated and expanded in vitro, making them amenable to manipulations, including the genetic correction of molecular defects. ES cells can be differentiated into a number of cells resembling mature cell types in vitro. In theory, cell therapy using donor cells of the same genetic constitution as the recipient may avoid the issues related to the immune barrier of allogeneic transplantation. One of the key ethical and practical barriers to applying ES cell research to human diseases is the need for obtaining human oocytes or embryos for the in vitro generation of ES cell lines.

A key finding with potential applications to cell and gene therapy has been the observation that many somatic tissues can be "reprogrammed" into pluripotent stem cells with characteristics of ES cells, termed iPS cells, and direct reprogramming of differentiated somatic cells by gene transfer of a small number of defined transcription factors has been shown to yield cells that are indistinguishable from inner cell mass-derived ES cells. Takahashi et al.[29] reasoned that forcing the expression of ES cell-specific genes, particularly transcription factors in somatic cells might induce (reprogram) somatic cells to take on the properties of ES cells, much like factors present in oocytes can reprogram somatic nuclei in mammals. By systematic screening experiments, four factors, including some known to be involved in the process of self-renewal (Oct3/4, Sox2), and others associated with transformation and maintenance of ES cell pluripotency (c-Myc, Klf 4), were identified as sufficient to achieve reprogramming. The resultant cells, termed iPS cells, exhibited key features of ES cells, including the fulfillment of stringent pluripotency requirements. This work was subsequently confirmed and expanded upon by other groups describing the application of this technology to human cells. Proof-of-concept for the utility of iPS cells in regenerative medicine of inherited blood disorders was recently provided when iPS cells were generated from tail tip fibroblast in a humanized sickle cell anemia mouse model. The genetic sickle hemoglobin defect of the iPS cells was corrected in vitro via homologous recombination. Using established protocols for the differentiation of hematopoietic progenitors from ES cells, hematopoietic cells capable of reconstituting lethally irradiated recipient mice were generated.

Transplantation of these cells into irradiated recipients resulted in robust engraftment and amelioration of the sickle cell phenotype in transplant recipients. Reprogramming of a panel of disease-specific human iPS cells, including patients with blood diseases, has been demonstrated. Human iPS cell lines shared defining features with human ES cells, including morphology, proliferation, feeder dependence, surface markers, gene expression, promoter and telomerase activities, in vivo differentiation, and teratoma formation. In analogy to the murine system, the reprogramming viruses are strongly silenced in human iPS cells, indicating that the maintenance of pluripotency does not depend on continuous transgene expression. Enforced transgene expression appears to initiate a sequence of stochastic events over several days that eventually induces a small fraction of cells (0.001% to 0.5% of cells) to acquire a stable pluripotent state. During direct reprogramming, gradual changes lead to a stable epigenetic state that is indistinguishable from inner cell mass-derived ES cells. For example, the Dnmt3a and Dnmt3b methyltransferases become activated and silence the viral transgenes as endogenous pluripotency factors are transcriptionally reactivated. Human iPS cell lines thus represent a novel stem cell population that can be studied with regard to normal and pathologic tissue formation in vitro, enabling disease investigation, drug development, and a platform for producing autologous cell therapies that avoid immune rejection. Moreover, the creation of iPS cells allows the correction of genetic defects and extensive molecular characterization at the clonal level before tissue reconstruction. While the genetic transduction with exogenous genes, particularly oncogenes such as *c-MYC* and *KLF4*, and the use of integrating retroviral delivery systems are clear handicaps of this technology with regard to future clinical translation, newer methods have utilized non-integrating vectors and even mRNA transduction to generate iPS. However, to date, robust reconstitution of murine hematopoiesis has not been consistently demonstrated, and there are no successful reports of in vivo reconstitution of human hematopoiesis in model systems. These all represent significant barriers to the translation of this powerful technology into human therapies.

One utility of targeting iPS cells for genetic therapies is that these cells can be cloned and expanded, allowing analysis of vector insertion sites before clinical use. In addition, reprogramming has now been accomplished, albeit at lower efficiencies using both non-integrating vectors and protein transduction. Reprogramming has also now been accomplished with the expression of fewer transcription factors, most notably without c-Myc. Several laboratories have demonstrated that targeting specific loci is associated with limited or no adverse effects on the expression of neighboring genes (reviewed by Sadelain et al.[30]). For example, targeting of the *AAVS1* locus located on chromosome 19 has been well characterized. This locus encodes the *PPP1R1C* gene that is ubiquitously expressed. Insertion at this site appears to provide a "safe harbor" with respect to genotoxicity and allows stable and long-term expression of transgenes in human ES cells (hHSCs). Finally, Naldini and colleagues have demonstrated that targeted insertion into two genomic sites (*IL2RG* and *CCR5*) using zinc-finger technology leads to no detectable alteration in the expression of nearby genes and sustained expression of the transgene cargo. The frequency of directed site-specific integration in primary fibroblasts was as high as 10%.[31] In addition, elegant work by Sadelain and colleagues[32] has demonstrated the feasibility of screening large numbers of iPS-derived clones for both integration in operationally defined safe harbors and for clinically relevant transgene expression using vectors that express globin genes.[32] Thus, this approach offers exciting future applications in treating a variety of human diseases.

Site-Directed Homologous Recombination to Correct Gene Mutations

A long-standing but unrealized goal of genetic therapy has been homologous recombination to affect the *replacement* of abnormal disease-causing gene mutations. Although human ES cells theoretically provide an ideal target for such correction, gene targeting in these cells has proven difficult. Zinc-finger nuclease (ZFN)-mediated DS breaks allow high-efficiency site-specific homologous recombination and has been used to target a number of genes in human cells. ZFNs are generated by fusing the FokI nuclease domain to a DNA recognition domain composed of engineered C2H2 zinc finger motifs that specify genomic DNA binding sites for the chimeric protein. Compared with standard homologous recombination vectors, one advantage of ZFN is the relatively short stretch of homology needed (500 bp vs. 10 to 12 kb) to mediate genomic targeting. The binding of two fusion proteins to cognate DNA allows dimerization of the nuclease, leading to the generation of a DS DNA break. When donor DNA with homology to sequence flanking the DS break is present, repair occurs with the incorporation of the incoming DNA sequence. This system has been successfully used to target genes in multiple species and has recently been demonstrated in both human ES cells and iPS cells to effectively target both expressed and nonexpressed genes with a frequency of 1% to 20% and has been termed *genome editing*. Because the development of a DNA DS break is a prerequisite to ZFN-mediated gene editing and such breaks induce both p53 and HDR, this approach, although attractive, could also have significant "off-target" effects. In addition, as efficiency improves, direct targeting in HSC is possible and a trial is currently under development to utilize ZFN-mediated deletion of *BCL11A*, which represses fetal hemoglobin expression in HSC, for the treatment of β-thalassemia.[33]

Other systems that seek to target specific genetic loci have also been described and are at different levels of development. As with ZFN nucleases, these approaches use cellular DNA repair mechanisms to introduce exogenous DNA sequences into the chromosome. Thus, methods to increase the efficiency of targeting by introducing DNA DS breaks, and several methods have exploited endonucleases that target rare DNA sequences to establish these DS breaks. Alternative methods in development include meganucleases and transcription activator-like effector nucleases.[34] Even more recently, bacterial immunity-related CRISPRs have shown higher efficiencies of genome editing by expressing the Cas9 protein and guide RNAs to target mammalian genomes at specific locations. Challenges of all of these approaches include efficiency of targeting in primary cells and potential off-target effects on the genome and will likely also depend on technological advances that allow ex vivo HSC cloning and large-scale expansion. These technologies have now developed at a scale and efficiency that has led to the first in human trials in thalassemia and SCD, with particularly noteworthy recent studies using CRISPR technology published in a very limited number of patients.[26]

New genome editing tools called base editors, which induce the targeted conversion of individual nucleotides, have been generated by fusing inactive Cas9 to deaminases which catalyze the enzymatic conversion of C to T (G-to-A on the opposing strand) or A to G (T-to-C on the opposing strand). This method does not induce DNA double-strand breaks and could thus be considered safer for use in therapeutic applications. The latest addition to the base editing repertoire, "prime" editing, has the ability to catalyze arbitrary nucleotide exchanges including correction of the sickle mutation. It consists of a fusion between a catalytically impaired Cas9 and an engineered reverse transcriptase, which directly copies the corrected sequence from an extended guide RNA into the target genomic locus. The proof of principle for the efficient correction of the sickling mutation has been shown in cell lines with up to 52% of gene correction. This technology will certainly undergo refinement, further optimization and characterization for use in patient HSCs in the near future.

FUTURE DIRECTIONS

The use of gene transfers to treat human diseases has now been successful in several diseases. Compared with allogeneic BMT, ex vivo gene therapy using autologous cells obviates the need to search for an appropriate donor, eliminates the risk of GVHD and in some cases reduces the intensity of the preparative regimen required before transplant, which also reduces toxicity. Thus, in some diseases, this therapeutic approach can now be considered an alternative to standard therapy. Insertional mutagenesis, which has resulted in serious adverse events in several trials, has stimulated the rapid development of putative safer vector systems that are being tested in human trials, but remains a challenge. Rapid progress in molecular technology, such as high-throughput sequencing, high-efficiency gene editing and the development of new sources of expandable stem cell sources, offers significant potential for ongoing development of gene transfer in regenerative biology for a wide range of human conditions.

CHAPTER 105

INDICATIONS, OUTCOMES, AND DONOR SELECTION FOR ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION FOR HEMATOLOGIC MALIGNANCIES IN ADULTS

Saurabh Chhabra, Mehdi Hamadani, and Parameswaran N. Hari

BACKGROUND

Early reports of leukemia-free survival, following human leukocyte antigen (HLA)-identical sibling hematopoietic cell transplantation (HCT) for refractory acute leukemia, was reported in the 1970s. Since then, allogeneic HCT has evolved into an effective and increasingly safe, curative, and intent therapeutic modality for hematologic malignancies.[1] The indications and applicability of HCT for specific diseases change over time, especially as non-transplant treatment options and our understanding of disease biology improve. For example, in chronic myelogenous leukemia (CML), molecularly targeted therapy has almost completely replaced HCT since the early 2000s. At the same time, developments in HCT, such as the advent of reduced intensity conditioning (RIC), the use of mismatched, haploidentical-related donor and cord blood grafts, and improvements in supportive care, have increased the scope and applicability of allogeneic HCT. Allogeneic HCT is increasingly used in older patients, ethnic minorities, those for whom fully HLA-matched donors are not available, and those in whom fully HLA-matched donors are used as a salvage strategy after relapse. Transplant-related mortality (also referred to as non-relapse mortality [NRM]), despite declining over the years, remains an important challenge; posttransplant relapse has emerged as a major therapeutic focus. General principles, indications, donor selection, and optimal timing of allogeneic HCT for hematologic malignancies in adults and post-HCT outcomes are discussed in this chapter.

Allogeneic HCT involves administration of a conditioning (or preparative) regimen of chemotherapy (with or without radiation) and immunosuppressive medications, followed by infusion of donor hematopoietic progenitor cells. Most patients then receive several months of immune suppression therapy to prevent or treat graft-versus-host disease (GVHD). The purpose of the conditioning regimen is twofold: to eradicate malignant cells and to eliminate host immune cells (capable of rejecting even HLA-identical sibling donor cells). The ability to restore hematopoiesis with donor hematopoietic progenitor cells permits the administration of substantially higher (myeloablative) doses of cytotoxic therapy, than is otherwise possible. Additionally graft-versus-malignancy (GVM) effects, conferred by alloreactive donor immune cells, contribute substantially to cancer eradication and relapse prevention.[2]

PATIENT POPULATION

The Center for International Blood and Marrow Transplant Research (CIBMTR) collects data on HCT outcomes from over 500 worldwide participating centers and on all allogeneic transplants in the United States.[3] Approximately 83,700 allogeneic HCT were performed in the United States between 2010 and 2018.[4] In 2018, approximately 2371 matched sibling donors, 4309 unrelated adult donors, 1503 haploidentical donors (defined as a related donor with two or more antigen mismatches), and 466 cord blood transplants were performed in the United States,[4] including approximately 7500 in adult patients. Hematologic malignancies are the most common indications for allogeneic HCT. Acute myeloid leukemia (AML), myelodysplastic syndrome/myeloproliferative neoplasms (MDS/MPN), and acute lymphoblastic leukemia (ALL) currently constitute the three most common indications of allogeneic HCT (Fig. 105.1).

In recent years, improved supportive care and the use of RIC have led to an increase in allogeneic HCT for older adults. Only 4% of allogeneic HCT-recipients, from 1987 to 1992, were older than 50 years. In 2018, 45% were older than 55 years and 20% were 65 years or older. The use of allogeneic HCT in patients 70 years and older in the United States increased substantially in the past decade, from 5 (0.1%) in 2000, to 283 (3.85%) in 2013.[5] Allogeneic transplantation, in patients without HLA-identical siblings, was facilitated by establishment of large unrelated donor registries around the globe. From 1987 to 1992, less than 10% of HCTs, for hematologic malignancies, used unrelated donors; in 2018, this figure was approximately 80%. Increased utilization of HCT among older adults, increasing use of unrelated donors, and more recently, haploidentical-related donors have been the main reasons for the steady growth in allogeneic HCT over the last decade. In 2011, approximately 300 haploidentical-related donor transplants were reported to the CIBMTR, compared with nearly 1500 transplants in 2018. The number of cord blood transplants declined concomitantly from a high of 816 in 2011, to approximately 500 in 2018. Over the years in the United States, the increase in the number of allogeneic HCT has been most striking in African Americans, while the number of allogeneic HCT for all indications increased by 7% from 2010 to 2018 for White people, the growth was 63% for African Americans, and 21% for Hispanics.[4] A threefold increase occurred between 2010 and 2018 in haploidentical HCT; in 2018, approximately 20% of haploidentical HCT were performed in African Americans.

CONDITIONING REGIMENS

Historically, conditioning regimens included myeloablative doses of cytotoxic drugs—with or without radiation—intended to provide disease control and induce host immunosuppression (to prevent graft rejection). Myeloablative conditioning (MAC) regimens for hematologic malignancies often involve a combination of cyclophosphamide (commonly 60 mg/kg/day for 2 days) and either busulfan (typically 3.2 mg/kg/day intravenously for 4 days or a similar pharmacokinetic guided dose) or, historically, conditioning regimens included total body irradiation (TBI) (5 to 15 Gy, single or fractionated doses). Posttransplant survival rates are broadly similar with either of the above approaches, although an advantage for pharmacokinetic-guided busulfan regimens has been shown for myeloid malignancies.[6] In a variety of regimens, other drugs such as fludarabine, etoposide, melphalan, and thiotepa are sometimes added to or substituted for cyclophosphamide and/or busulfan in efforts to provide better, generally disease-specific, antineoplastic activity. An Italian phase III randomized study in AML patients compared the two common MAC regimens (intravenous busulfan plus cyclophosphamide [BU CY],

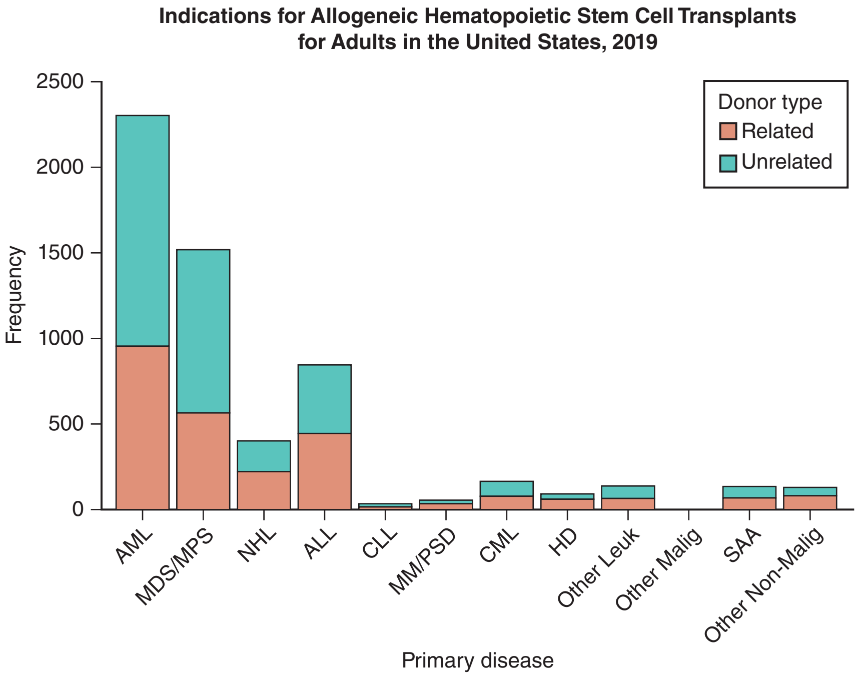

Figure 105.1 INDICATIONS FOR ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION IN ADULTS (US DATA), 2019. *ALL, Acute lymphoblastic leukemia; AML, acute myeloid leukemia; CLL, chronic lymphocytic leukemia; CML, chronic myeloid leukemia; HD, Hodgkin disease; Leuk, leukemia; Malig, malignancy; MDS, myelodysplastic syndrome; MM, multiple myeloma; MPS, myeloproliferative syndrome; NHL, non-Hodgkin lymphoma; PCD, plasma cell dyscrasia; SAA, severe aplastic anemia.*

with busulfan plus fludarabine [Flu BU]) and demonstrated lower NRM (with busulfan plus fludarabine), without affecting relapse risk.[7] In a study randomizing AML patients to high-dose cyclophosphamide and either 12 Gy or 15.75 Gy TBI as conditioning, a lower relapse risk in the 15.75 Gy TBI group was offset by higher NRM risk leading to similar OS.[8] A more recent CIBMTR study also reported that higher doses of TBI over the standard dose (12 Gy) were associated with worse NRM and offered no survival benefit.[9]

Toxicity associated with MAC regimens can be minimized and efficacy can be improved with careful pharmacokinetic monitoring of certain drugs, for example, busulfan. Another strategy for lowering NRM is reducing the dose-intensity of the conditioning regimen. This approach uses lower doses of cytotoxic drugs and/or radiation to facilitate donor cell engraftment and relies more on GVM effects to eradicate malignant cells. The lower doses of cytotoxic agents produce less host tissue damage and inflammatory cytokine secretion, resulting in lower rates of regimen-related morbidity and mortality. In patients ineligible for traditional MAC regimens, the use of RIC regimens has greatly increased the applicability of allogeneic HCT because of age or comorbidities. The development of RIC regimens has led to a substantial increase in the utilization of HCT in older patients (Fig. 105.2).

Consensus criteria developed by the CIBMTR and the European Society for Blood and Marrow Transplantation (EBMT) distinguish between myeloablative, reduced intensity and nonmyeloablative regimens based on the likelihood of the regimen to produce toxicity in the recipient marrow (Table 105.1).[10] MAC regimens produce profound pancytopenia and are usually fatal in the absence of stem cell rescue. Nonmyeloablative regimens cause brief and often less severe pancytopenia, and in the absence of donor stem cell rescue, autologous hematopoietic recovery is likely to occur. RIC regimens are an intermediate category that does not fit well in either of the above, since they produce pancytopenia that may recover without stem cell rescue. RIC regimens induce less immune compromise in the immediate post-HCT setting as the duration and depth of neutropenia are reduced and host-derived immunocompetent cells are not immediately eliminated.[3,11]

It is generally accepted that RIC regimens allow HCT in some patients who are ineligible or not offered HCT with MAC. For example, in the United States, the proportion of transplants performed in patients 60 years and older increased from less than 5% before 2000, to ~34% in 2018. Two-thirds of the latter patients received RIC regimens. However, RIC regimens are increasingly used in patients of all ages who receive both related and unrelated donor transplants, as is shown in Fig. 105.2. Despite the growing popularity of RIC regimens, large retrospective database studies from the EBMT and CIBMTR (summarized in Table 105.2) have generally failed to show a definite survival advantage resulting from the use of such conditioning regimens. Although RIC regimens allow a potent graft-versus-leukemia response to occur with lower toxicity, there are concerns about a higher risk of disease relapse following RIC regimens. Since the distribution of conditioning regimens in registry studies reflects physician choice or patient selection bias, retrospective data are of limited value and randomized trials have addressed this question. The prospective US Bone Marrow Transplant Clinical Trial Network (BMT CTN) 0901 trial randomized patients with myeloid malignancies eligible for myeloablative conditioning to RIC versus MAC regimens. In this trial, a superior relapse-free survival was evident for MAC after enrolling 272 out of the planned 356 patients, leading to early closure of the study. Notably, an overall survival (OS) advantage did not emerge.[12] A prospective randomized European trial (RICMAC) showed similar 2-year, relapse-free, and overall survival for busulfan-based RIC versus MAC in patients with MDS and secondary AML.[13]

Donor Factors

NRM rates are generally lower after HLA-identical sibling than after unrelated donor or alternative donor transplants because of less graft failure, faster immune reconstitution, and less GVHD. However, considerable progress has been made in reducing NRM rates after both HLA-identical sibling and alternative donor HCT. For matched sibling donor HCT (for AML in CR1), the incidence of NRM at 1 year decreased from 23% from 1985 to 1989, to about 11% from

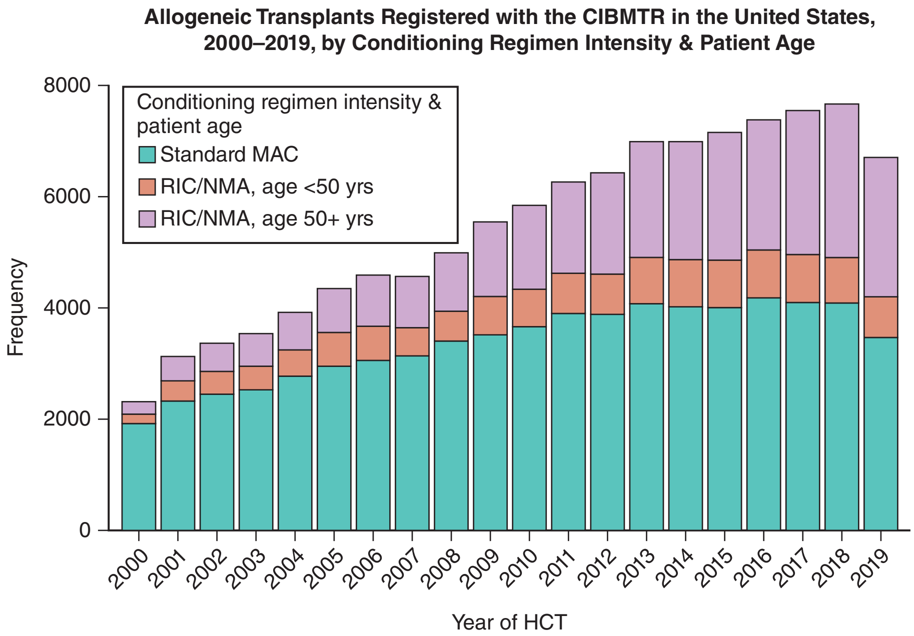

Figure 105.2 CONDITIONING REGIMEN INTENSITY AND PATIENT AGE: CHANGING TREND OVER TIME (2000–2019). *CIBMTR, Center for International Blood and Marrow Transplant Research; HCT, hematopoietic cell transplantation; MAC, myeloablative conditioning; NMA, nonmyeloablative; RIC, reduced intensity conditioning.*

TABLE 105.1 **Consensus Definition of Conditioning Regimen Intensity**

Myeloablative Conditioning
Profound Cytopenia, Not Likely to Recover Without Hematopoietic Cell Rescue
Total body irradiation >5 Gy single dose or >8 Gy fractionated
Busulfan >8 mg/kg orally or intravenous equivalent
Nonmyeloablative Conditioning
Minimal Cytopenia, Autologous Recovery of Hematopoiesis Likely Even Without Transplant
Total body irradiation <2 Gy + purine nucleoside analogue
Fludarabine + cyclophosphamide + antithymocyte globulin
Fludarabine + cytarabine + idarubicin
Cladribine + cytarabine
Total lymphoid irradiation + antithymocyte globulin
Reduced Intensity Conditioning
Regimens that are intermediate between the above categories

2000 to 2004, and down to 6.3% in 2018. The 1-year incidence of NRM for unrelated donor HCT (for AML in CR1) from 1990 to 1994 was 34%, which decreased to 26% from 2000 to 2004, and down to 9.5% in 2018.[14] Among alternative donor transplants, those from more closely HLA-matched donors tend to have lower risks of GVHD and NRM. Donor-recipient HLA mismatching is associated with increased risk of posttransplant complications, including graft rejection, acute and chronic GVHD, and mortality; risks increase progressively with multiple HLA mismatches. With modern molecular HLA typing techniques (allowing selection of more closely HLA-matched donors) and current GVHD prevention strategies, the difference in outcomes between HLA-matched sibling and unrelated donor transplantation has narrowed (Fig. 105.3). Adoption of molecularly defined, HLA matching techniques, calcineurin inhibitor–based GVHD prophylaxis, fungal prophylaxis with azoles, leukocyte reduction of blood products, newer assays for viral reactivation, pharmacokinetic testing of conditioning agents, and posttransplant cyclophosphamide for induction of allogeneic tolerance are some of the major innovations that have impacted NRM.

GRAFT SOURCES

The sources of hematopoietic cells for transplantation, historically bone marrow from donors, now also include peripheral blood hematopoietic cells, collected by leukapheresis and umbilical cord blood. The composition of grafts from bone marrow, peripheral blood, and cord blood varies in terms of the proportion of pluripotent stem cells, the proportion of lineage-committed late progenitor cells, and in the proportion and characteristics of immune-reactive cells. Bone marrow is the primary source of allogeneic donor cells for transplantation in children, and peripheral blood is the primary source in adults (Fig. 105.4).

Several randomized trials have compared matched-sibling bone marrow versus peripheral blood grafts in patients with hematologic malignancy, following MAC regimens. In general, these studies showed no difference in the rates of acute GVHD between the two graft sources and showed no difference between higher risk of chronic GVHD with peripheral blood grafts. While survival outcomes were similar in most studies, the US and Canadian randomized studies reported a disease-free and overall survival advantage, respectively, favoring peripheral blood grafts.[15,16] A meta-analysis, using individual patient-level data from nine randomized trials of related donor peripheral blood versus bone marrow transplants suggested that patients receiving peripheral blood grafts had faster hematopoietic recovery,[15] a lower relapse rate if transplanted for hematologic malignancy, and higher overall and disease-free survival if transplanted for advanced-stage disease. However, peripheral blood was also associated with a significantly increased risk of extensive chronic GVHD. Among unrelated donor transplant recipients, the prospective randomized BMT-CTN 0201 trial showed a higher risk of chronic GVHD in patients receiving peripheral blood grafts (53% versus 41% for marrow grafts).[17] Notably, survival and the incidence of relapse and acute

TABLE 105.2 Retrospective Registry-Based Comparisons of Nonmyeloablative/Reduced Intensity Conditioning Versus Myeloablative Allogeneic Hematopoietic Cell Transplantation

Group	Disease	Donor	RIC vs. MAC (*N*)	NRM RIC vs. MAC	Relapse	Comments
EBMT[161]	MDS or sAML, >50 years	UD 39%	833 vs. 500	32% vs. 44% at 4 years	41% vs. 33%	Survival 31% at 4 years. RIC predicted for greater relapse but lower NRM.
EBMT[162]	AML, >50 years	Sibling	315 vs. 407	18% vs. 32% at 2 years	41% vs. 34%	No difference in leukemia-free and overall survival between RIC and. MAC.
EBMT[163]	MM	MUD 12%	320 vs. 196	24% vs. 37% at 2 years	27% vs. 54%	NRM was lower after RIC but relapse risk was double.
EBMT[164]	AML	Sibling	215 vs. 621	22% vs. 32% at 3 years	45% vs. 27%	Relapse rate higher and NRM lower in RIC but OS similar (41% vs. 45%) in both groups.
EBMT[165]	CLL	MUD 22%	73 vs. 82	19% vs. 26%	28% vs. 11%	Similar NRM but higher relapse risk observed after RIC.
EBMT[166]	HL	MUD 13%	89 vs. 79	23% vs. 46% at 1 year	57% vs. 30%	Relapse rate was higher and NRM lower in RIC but OS was similar.
CIBMTR[167]	Follicular NHL	Sibling	88 vs. 120	23% in both at 1 year	17% vs. 8%	RIC associated with higher risk of relapse but similar NRM while lower KPS impacted on NRM. OS was similar.
EBMT[168]	ALL	Sibling	127 vs. 449	21% vs. 29%	32% vs. 38%	NRM lower after RIC but higher relapse rate. Leukemia-free survival similar to MAC.
EBMT[169]	AML	MUD	401 vs. 1154	<50 years: 25% vs. 27%;≥50 years: 25% vs. 39% at 2 years	<50 years: 38% vs. 30%;≥50 years: 42% vs. 29%	RIC (vs. MAC) was associated with higher relapse <50 years and decreased NRM ≥50 years. Leukemia-free survival was similar after both RIC and MAC, regardless of age.
CIBMTR[170]	AML/MDS	MUD/ Sibling	1448 vs. 3731	3-year NRM similar	Lower risk of relapse in myeloablative	Overall and disease-free survival was highest for myeloablative group.
CIBMTR[119]	CML, 18–60 years	MUD/ Sibling	191 vs. 1204	29% vs. 32% at 5 years	25% vs. 26%	Similar leukemia-free and overall survival and lower chronic GVHD risk with RIC vs. MAC in TKI era.

ALL, Acute lymphoblastic leukemia; *AML*, acute myeloid leukemia; *CIBMTR*, Center for International Blood and Marrow Transplant Research; *CLL*, chronic lymphocytic leukemia; *EBMT*, European Society for Blood and Marrow Transplantation; *GVHD*, graft-versus-host disease; *HCT*, hematopoietic cell transplantation; *HL*, Hodgkin lymphoma; *KPS*, Karnofsky performance score; *MAC*, myeloablative conditioning; *MDS*, myelodysplastic syndrome; *MM*, multiple myeloma; *MUD*, matched unrelated donor; *NHL*, non-Hodgkin lymphoma; *NMA*, nonmyeloablative; *NRM*, non-relapse mortality; *OS*, overall survival; *RIC*, reduced intensity conditioning; *sAML*, secondary acute myeloid leukemia; *TKI*, tyrosine kinase inhibitors.

GVHD were similar, while graft failure was more common among recipients of marrow grafts.[17] The relative importance of graft sources in patients receiving lower-intensity conditioning is not known, but a CIBMTR study comparing unrelated bone marrow versus peripheral blood grafts, following RIC, showed no difference between the two sources in terms of rates of acute or chronic GVHD, relapse risk, and survival outcomes.[18]

Donor Selection

While donor-derived alloimmunity in the form of a graft versus tumor effect leads to tumor control, the same phenomenon directed against normal host tissues leads to GVHD, which is a major determinant of NRM after allogeneic transplantation. The major criterion for selecting an allogeneic donor is the degree of histocompatibility between the donor and recipient because the risks of both graft rejection and GVHD increase with the degree of genetic disparity.[19–21] Alloreactivity is reduced by matching recipients and donors at loci in the major histocompatibility complex (MHC), including HLA that is encoded by class I (*HLA-A*, *HLA-B*, and *HLA-C*) and class II (*HLA-DR*, *HLA-DQ*, and *HLA-DP*) genes. HLA molecules were originally defined by serology, but DNA-based, high-resolution testing is now routine.[22] Even in the setting of MHC-matched, donor-recipient pairs, minor histocompatibility antigen (MiHA) (cell surface peptides found in association with class I or II MHC molecules) differences that are detectable by T cells can stimulate an MHC-restricted, alloreactive response, resulting in GVHD. The optimal donor is a sibling sharing HLA class I and HLA class II alleles, but matched sibling donors are available for only about 30% of patients.

For unrelated donor HCT, the primary driver for successful outcome is the degree of donor-recipient HLA matching. In 1986, the National Marrow Donor Program (NMDP; "Be the Match Registry") was established as a repository for HLA typing information so that unrelated donors and recipients could be adequately matched.[23,24] The NMDP HapLogic donor search considers over 20 million donors (87% typed for HLA-A, HLA-B, and HLA-DR) and additionally provides a match report of an additional 13 million donors listed in World Marrow Donor Association Search and Match.[25] Such a large number of donors is necessary because great diversity exists in the HLA system, with over 5500 class I alleles (*HLA-A*, *-B*, and *-C*) and over 1600 class II alleles (*HLA-DRB1* and *-DQB1*), resulting in several million potential HLA combinations.[26] The likelihood of finding an optimal adult unrelated donor (i.e., a donor matched at high resolution at *HLA-A, HLA-B, HLA-C*, and *-DRB1* alleles or a "8/8 match") varies among racial and ethnic

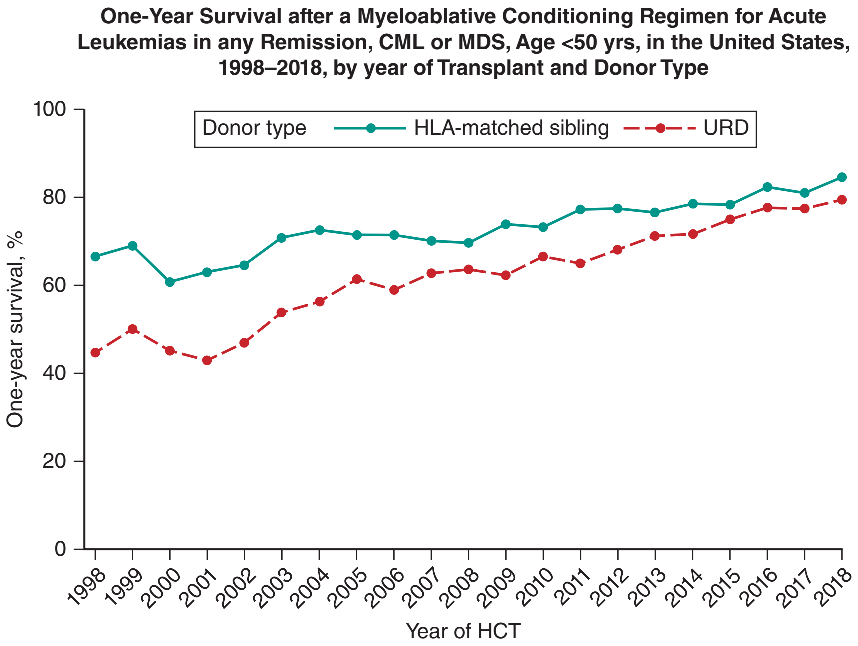

Figure 105.3 ONE-YEAR SURVIVAL AFTER MYELOABLATIVE HCT IN YOUNGER PATIENTS (RELATED VERSUS UNRELATED DONOR). *CML, Chronic myeloid leukemia; HCT, hematopoietic cell transplantation; HLA, human leukocyte antigen; MDS, myelodysplastic syndrome; URD, unrelated donors.*

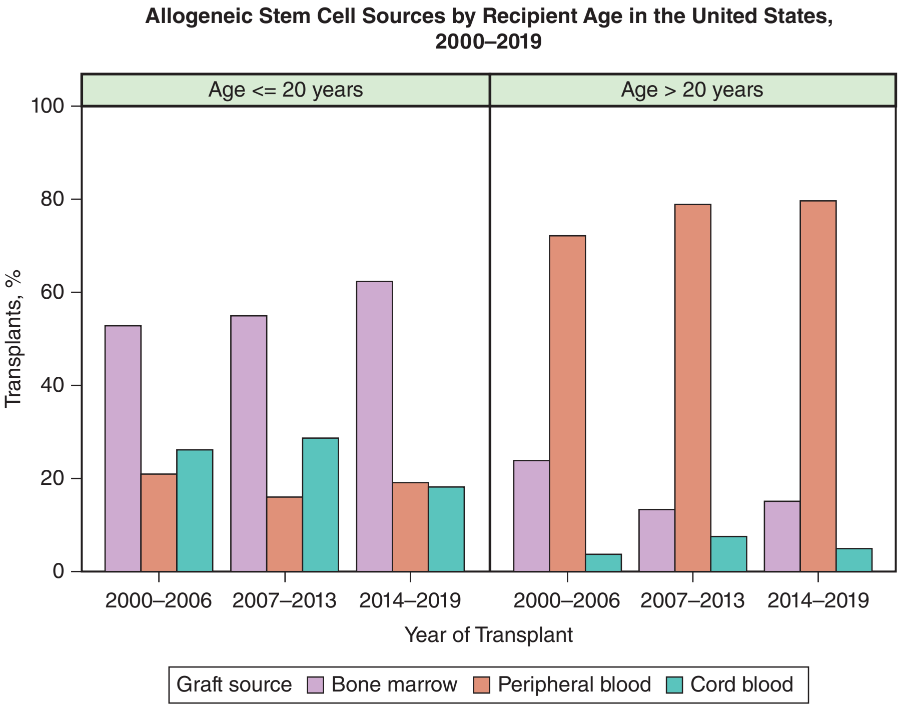

Figure 105.4 ALLOGENEIC STEM CELL SOURCES, BY DONOR TYPE VERSUS DONOR AGE, 2000–2019.

groups, depending on the size and composition of unrelated donor registries. Within the US population, the highest likelihood for finding an optimal donor is 75% for White people of European descent, and the lowest is 16% among Black people of South or Central American descent.[27] The development of large donor registries has expanded access to transplantation, as well as increasing the likelihood that a recipient will find a well-matched donor.[28] However, this also means that patients who do not find a suitably matched donor in the large registry pool have rare HLA genotypes for whom waiting for a fully matched donor from among new additions recruited to the donor pool is not recommended. Such patients should proceed to alternative donor transplantation with partially matched sources; haploidentical or cord blood donor grafts.

The adoption of high-resolution HLA typing for matching and selection of unrelated donors, have been associated with improved outcomes.[20,29–32] A study examining unrelated donor characteristics predictive of outcomes reported that after adjusting for the disease and comorbidities, when the donor was a 10/10 match (matched for *HLA-A, -B, -C, -DRB1*, and *-DQB1*). Age is the most important factor, after donor-recipient HLA match: survival was significantly improved if the donor was young (aged 18 to 32 years).[33] A 5.5% increase occurred in the hazard for overall mortality for every 10-year increment in donor age. If multiple 8/8 matched unrelated donors are available, other factors could be considered, such as donor age, matching at DPB1 or permissive DPB1 mismatching, avoidance of donor allotypes targeted by donor-specific antibodies in the recipient, and blood group or CMV-status matching. With current high-resolution HLA typing and donor selection, unrelated donor transplants have survival comparable to that of matched sibling donor setting.[34–37]

For patients lacking a matched sibling or 8/8 matched unrelated donors, the options are a mismatched and unrelated donor, a haploidentical-related donor, or a cord-blood unit (collectively denoted as "alternative donors"). Each choice has benefits and disadvantages (Table 105.3). As a source of donor hematopoietic cells, umbilical cord blood offers several advantages. It is readily available as cryopreserved units, entails no risk to the donor and the HLA-matching criteria for cord blood transplantation need not be as stringent as for adult donor transplantation. Hence, mismatched cord blood units, at one or two HLA loci, are available for almost all patients less than 20 years of age and for more than 80% of patients ≥20 years of age, regardless of racial and ethnic background.[9,27] Drawbacks of cord blood transplantation include procurement costs, such as the fixed and often limited dose of hematopoietic cells (based on recipient body weight) in each cord blood unit and relatively high rates of NRM. However, double cord blood transplantation, with each unit sharing at least 4/6 HLA antigens with the recipient, has been shown to overcome the problem of dose and extend the use of cord blood transplant to adult patients.[38] Other approaches to facilitate engraftment with limited cord blood cell doses, including ex vivo cell expansion techniques, are in clinical trials.[39]

HLA haploidentical-related donor HCT is another option for patients without matched siblings or unrelated donors. Haploidentical donors are usually parents, siblings, or children of patients who are mismatched at ≥2 loci *HLA-A, HLA-B, HLA-C*, and *HLA-DRB1*. Historically, T-cell-replete haploidentical HCT was prohibited by severe GVHD and NRM, approaching 50%.[40] Haploidentical HCT have been made significantly safer by the administration of high-dose cyclophosphamide after transplantation (posttransplant CY), which promotes tolerance by elimination of alloreactive host and donor T cells, leading to suppression of graft rejection and GVHD, without toxicity to donor hematopoietic cells.[41,42] Immediate and near-universal donor availability and theoretically lower costs are advantages of haploidentical grafts. Several retrospective registry analyses suggest haploidentical HCT, performed using T-cell-replete grafts and posttransplant cyclophosphamide, achieves outcomes comparable with those of transplantation performed using matched related or unrelated donors.[44–50] An increased risk of NRM has been suggested in patients receiving haploidentical HCT, using posttransplant CY compared with matched sibling donor HCT and calcineurin-inhibitor-based[51] or posttransplant cyclophosphamide-based GVHD prophylaxis.[52] These data caution against using haploidentical-related donors in lieu of adult, matched-related donors outside of a clinical trial.

TABLE 105.3 Donor Choice

	Mismatched Unrelated Donor	Haploidentical Donor	Cord
Availability	Over 80%	Over 95%	Over 80%
Time to procure	1–4 months	Immediate	2–5 days
Engraftment	Over 95%	Over 95%	Over 90% with slower engraftment
GVHD	Moderate	More genetic disparity but moderate with most modern regimens	Moderate—may be less acute but chronic similar
Availability donor for posttransplant immune therapy	Usually, but takes 2–4 weeks	Yes	No
Relative cost	Moderate	Low if unmanipulated product. Moderate if ex vivo selection	Moderate (1 unit) or high (2 units)
Risk of relapse	Moderate	Higher with regimens that are effective in preventing GVHD	Moderate

GVHD, Graft-versus-host disease.

In patients lacking adult, 8/8-matched (sibling or unrelated) donors, the choice between cord blood versus haploidentical HCT has been a matter of much debate. The phase III randomized BMT-CTN 1101 study compared double umbilical cord blood versus haploidentical marrow grafts and reported that NRM and overall survival at 2 years were superior in patients who received haploidentical marrow transplantation, while there was no significant difference in the primary endpoint of progression-free survival between the two types of transplant.[53] Other techniques for facilitating haploidentical transplants have been developed around the world that involve combinations of selective T-cell depletion ex vivo, mega dose infusion of CD34 progenitors, or induction of immune tolerance with G-CSF and anti-thymocyte globulin (ATG).[54,55]

In a minority of patients, especially those with donor-specific, anti-HLA antibodies (DSAs), appropriate cord and haploidentical donors may be unavailable. Unrelated donor grafts, mismatched at more than one allele, have now emerged as an alternative source in the context of post-transplant CY-based GVHD prophylaxis, similar to haploidentical-related donor HCT.[56,57] A single-center study among recipients of nonmyeloablative conditioning for HCT from mismatched unrelated donors (majority at two or more loci), using posttransplant CY/sirolimus and mycophenolate as GVHD prophylaxis, demonstrated a promising 2-year NRM and overall survival of 6% and 67%, respectively.[58]

Graft-Versus-Host Disease Prophylaxis

The combination of a calcineurin inhibitor, such as cyclosporine, tacrolimus, or methotrexate, has been the mainstay of GVHD prevention, after allogeneic HCT.[59–63] For RIC regimens, an acceptable alternative is a combination of a calcineurin inhibitor and mycophenolate mofetil.[64–66] Despite GVHD prophylaxis, over 50% of allogeneic HCT recipients will develop acute and/or chronic GVHD. Studies have demonstrated that in vivo T-cell depletion with anti-thymocyte ATG can reduce chronic GVHD,[67] though the effect on survival has been questioned. Prospective phase III randomized trials have compared the use of ATG as part of GVHD prophylaxis in unrelated and related donor HCT and generally suggest lower rates of acute and/or chronic GVHD, without an impact on relapse, survival, or NRM.[68–71] Comparisons are difficult due to differences in clinical trial designs, potency, dosage of ATG preparations due to different production methods, and absolute lymphocyte count at the time of ATG administration.[72,73]

Administration of cyclophosphamide after HCT has moved from early use in the haploidentical HCT setting to the HLA-matched, related and unrelated donor HCT settings.[74–76] A prospective phase III randomized HOVON-96 trial done with recipients of matched-donor grafts in the RIC setting reported a significant reduction in both acute and chronic GVHD and 1-year GVHD-free and relapse-free survival with the use of post-transplant cyclophosphamide, without any difference in progression-free and overall survival.[77] The control arm in this study utilized cyclosporine and mycophenolate, which precludes comparison with the more common methotrexate-based

GVHD prophylaxis approach, after RIC transplantation.[64] A phase II randomized BMT CTN 1203 trial also suggested improved GVHD-free and relapse-free survival, along with lower risk of severe acute and chronic GVHD for post-transplant, CY-based GVHD prophylaxis regimen in RIC HCT, compared with non-randomized contemporaneous controls.[78] A large randomized trial of post-transplant cyclophosphamide versus the current standard of tacrolimus and methotrexate is now enrolling patients (BMT CTN 1703).

IMPACT OF MEASURABLE RESIDUAL DISEASE

At the time of transplant, disease remission status is a strong predictor of survival post transplantation for hematologic malignancies. Evaluation of measurable or minimal residual disease (MRD) status, using sensitive techniques (multiparameter flow cytometry, sequencing), is one of the most important established prognostic tools in ALL and is now emerging to be an important predictive and prognostic marker in other hematologic malignancies, such as AML, myeloma, and B-cell lymphomas. In ALL, MRD is present in up to 30% to 50% patients in a traditional CR.[79,80] Consideration of MRD impacts several clinical decisions in HCT. Among these are: assessing the suitability of proceeding to HCT versus additional consolidative therapy in patients who achieve a traditional CR but with residual MRD, the intensity of conditioning regimen used for HCT (RIC versus MAC), the role of pre-emptive posttransplant therapy to address relapse risk, and the need for HCT in those with an MRD-negative remission.

PREVENTION OF RELAPSE AFTER ALLOGENEIC TRANSPLANTATION

Primary causes of death after allogeneic HCT for hematologic malignancies are shown in Fig. 105.5. With improvements in prophylaxis and treatment of GVHD and supportive care advancements, relapse is now the leading cause of transplant failure. Maintenance therapy administered to patients in remission and after HCT attempts to reduce the risk of relapse. The ideal maintenance agent should have minimal interference with GVM effects, should not incite GVHD, nor interact with routine posttransplant drugs and should be tolerable with an acceptable toxicity profile. Targeted agents with minimal off-target toxicities, the list of potential maintenance options is growing. Maintenance therapy in Philadelphia chromosome-positive (Ph+) leukemias, including chronic myeloid leukemia and Ph+ ALL, comprises Abelson tyrosine kinase inhibitors (TKIs), based on single-arm studies and retrospective evidence supporting their adoption as the current standard.[81–84] In AML, the presence of an FMS-like tyrosine kinase internal tandem duplication (FLT3-ITD) mutation predicts for higher relapse risk, even after HCT in first complete remission (CR1). Gilteritinib, a selective FLT3 TKI approved for relapsed/refractory AML treatment, is being evaluated as post-HCT maintenance in a phase III randomized, double-blind, placebo-controlled trial (BMT CTN 1506). A non-targeted maintenance approach for AML and MDS with hypomethylating agents has been demonstrated to be feasible in several single-arm prospective trials and retrospective case series, but the efficacy of this strategy still needs to be proven in a phase III randomized trial.[85–88] Maintenance using novel targeted agents, such as IDH inhibitors, are also expected to be tested in specific molecular subtypes in the future.

Timing of Transplantation

In general, HCT outcomes are better when transplantation is done earlier in the disease course. Transplantation for advanced disease is associated with higher risks of both relapse and NRM. High NRM, in the setting of advanced disease, likely reflects patients' poorer clinical status and the cumulative effects of more extensive prior treatment. Since some HMs have excellent prognosis with non-transplant therapy (e.g., children with standard-risk ALL or adults with acute promyelocytic leukemia), appropriate timing of transplantation requires consideration of likely outcomes with transplant and non-transplant therapies. However, even when not used early, transplantation should not be

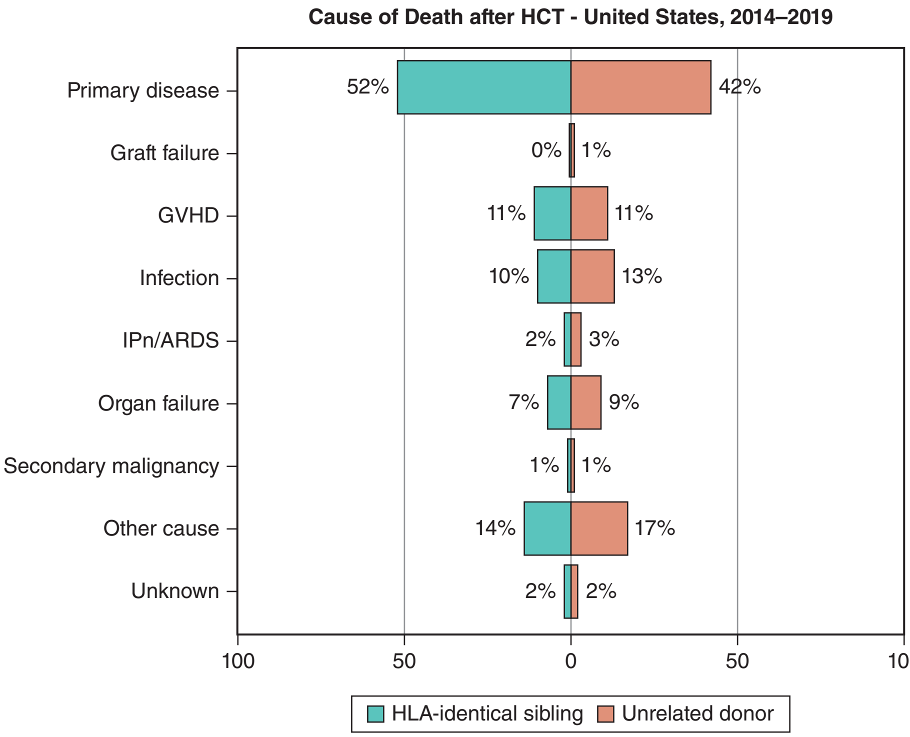

Figure 105.5 CAUSES OF DEATH AFTER TRANSPLANTATION, 2014–2019. *ARDS, Acute respiratory distress syndrome; GVHD, graft-versus-host disease; HLA, human leukocyte antigen; IPn, idiopathic pneumonia syndrome.*

inordinately delayed, since patients with refractory disease or severe complications from extensive prior therapy are unlikely to benefit. For patients with diseases potentially curable by allografting, appropriate timing of transplantation should be considered early in the overall management strategy. This includes early determination of donor availability. The American Society for Transplantation and Cellular Therapy (ASTCT) has developed evidence-based guidelines (Box 105.1), based upon current clinical practice and available literature (available online at https://www.astct.org/practice/practice-guidelines).[89]

Patient- and Disease-Related Factors

NRM is lower and, consequently, survival higher, in patients who are young, cytomegalovirus antibody screen-negative, have good performance scores, and have no active infection. While age is still a significant barrier to successful allogeneic HCT, the presence and extent of medical comorbid conditions rather than an arbitrary chronologic age cutoff, is increasingly recognized as a major determinant of NRM. Box 105.2 depicts the commonly used HCT-Comorbidity Index (HCT-CI), used for estimating risk of NRM.[90] Although many factors influence the outcome of allogeneic HCT, disease type and disease status at the time of transplantation are the strongest disease-related determinants of post-transplant survival. The CIBMTR Refined Disease Risk Index (R-DRI) (Box 105.3) is a validated prognostic tool that predicts overall survival after allogeneic HCT, based on patient's disease type and remission status.[91] Both HCT-CI and R-DRI are increasingly used in clinical decision making to determine patient eligibility and optimal conditioning intensity pre-HCT.

BOX 105.1 American Society for Transplantation and Cellular Therapy Indications for Allogeneic Transplantation in Adults (see full recommendations at https://www.astct.org/learn/practice-guidelines)

The ASTCT committee on practice classified the proposed indications for transplant as "standard of care" (S) or "clinical evidence available" (C), or "rare indication" (R). Emerging indications still in experimental stages were noted as "developmental" (D).

Disease State	Policy Regarding: Allogeneic Transplantation
AML in adults	• Standard-of-care for patients with AML with intermediate and high risk who are in CR1, for treatment of AML in ≥CR2 and for AML patients not in remission (all S) • Recommended for patients with therapy-related AML in CR1 (S) • Allogeneic HCT was not recommended for AML patients with low-risk disease and CR1
Acute promyelocytic leukemia	• Recommended for patients with APL in CR2 and with lack of molecular remission (S) • Clinical evidence supports allogeneic HCT for APL in CR2 with molecular remission, CR≥3, patients not in remission and patients relapsing after prior autologous HCT (all C) • Allogeneic HCT not recommended for APL patients in CR1
ALL	• Recommended as standard-of-care for treatment of ALL patients with standard-risk and high-risk in CR1, and patients with CR≥2 (all S) • For patients with ALL who are not in remission, allogeneic HCT can be considered (S)
CML	• Recommended as standard-of-care for patients with CML in CP2+, accelerated and blast phase (all S) • Standard-of-care with clinical evidence for CML patients in CP1, if refractory to or intolerant to multiple TKIs (C)
Myelofibrosis and myeloproliferative diseases	• Evidence supporting allogeneic HCT for treatment of patients with low-, intermediate- and high-risk primary disease and for secondary myelofibrosis (all C). Hypereosinophilic syndrome is a rare indication (R)
Myelodysplastic syndrome	• Recommended in highintermediate 2 risk disease (S) and recommended with clinical evidence in low/intermediate-1 risk (C)
Plasma cell disorders	• Considered standard-of-care for treatment of chemosensitive relapsed myeloma, including relapse after autologous HCT and for plasma cell leukemia (S) • There is developmental evidence to support allogeneic HCT for refractory myeloma (D)
Hodgkin lymphoma	• Allogeneic HCT is standard-of-care for chemosensitive first relapse, second or greater relapse and relapse after autologous HCT (all S) It can be considered for chemotherapy resistant first relapse, primary refractory disease; (all C) • Allogeneic HCT not recommended for Hodgkin lymphoma in CR1
DLBCL	• Allogeneic HCT is standard-of-care for primary refractory DLBCL (sensitive- or resistant-), first relapse (sensitive- or resistant-), second or greater relapse, and relapse after autologous transplant (all S). • There is insufficient evidence to recommend allogeneic HCT for high-grade B cell lymphoma, with MYC and BCL2 and/or BCL6 rearrangements, in CR1 and for primary central nervous system lymphoma in CR1 or in relapse
Follicular lymphoma (FL)	• Recommended as standard-of-care for primary refractory (resistant) FL, first relapse (resistant), and second or greater relapse, including relapse after autologous transplant (all S) • There is sufficient evidence to recommend allogeneic HCT for FL transforming to high-grade lymphoma. • Allogeneic HCT is not recommended for FL in CR1, first relapse (sensitive), including progression within 2 years
Mantle cell lymphoma (MCL)	• Recommended as standard of care for primary-refractory (sensitive) MCL, sensitive first relapse, second or greater relapse, and relapse after autologous transplant (all S) • There is evidence to support use of allogeneic HCT CR1/first partial remission, primary refractory (resistant) and first relapse (resistant) MCL (all C)
T-cell lymphoma	• Recommended as standard-of-care for CR1/first partial remission, primary refractory (sensitive), chemosensitive first relapse, second or greater relapse, and relapse after autologous HCT (all S) • Allogeneic HCT may also be considered for primary refractory (resistant) and chemoresistant first relapse (all C) • Allogeneic HCT is considered standard-of-care for relapsed cutaneous T-cell lymphoma (S)
Chronic lymphocytic lymphoma (CLL)	• Recommended as standard-of-care for high-risk CLL, first or greater remission and T-prolymphocytic leukemia (all S) • There is sufficient evidence to recommend allogeneic HCT for transformation to high-grade lymphoma (C)

ALL, Acute lymphoblastic leukemia; *AML*, acute myeloid leukemia; *CR*, complete remission; *DLBCL*; diffuse large B-cell lymphoma; *HCT*, hematopoietic cell transplantation.

BOX 105.2 Hematopoietic Cell Transplantation-Specific Comorbidity Index

Comorbidity	Explanation	HCT-CI score
Arrhythmia	Atrial fibrillation or flutter, sick sinus syndrome, or ventricular arrhythmias	1
Cardiac	Coronary artery disease, congestive heart failure, myocardial infarction, or ejection fraction ≤50%	1
Inflammatory bowel disease	Crohn disease or ulcerative colitis	1
Diabetes	Requiring treatment with insulin or oral hypoglycemics	1
Cerebrovascular disease	Transient ischemic attack or cerebrovascular accident	1
Psychiatric disturbance	Depression or anxiety requiring psychiatric consult or treatment	1
Hepatic, mild	Chronic hepatitis, bilirubin > ULN to 1.5 × ULN, or AST/ALT > ULN to 2.5 × ULN	1
Obesity	Patients with a body mass index >35 kg/m$^+$	1
Infection	Requiring treatment after day 0	1
Rheumatologic	SLE, rheumatoid arthritis, polymyositis, mixed connective tissue disease, or polymyalgia rheumatica	2
Peptic ulcer	Requiring treatment	2
Moderate/severe renal	Serum creatinine >2 mg/dL, on dialysis, or prior renal transplantation	2
Moderate pulmonary	DLCO and/or FEV$_1$ 66% to 80% or dyspnea on slight activity	2
Prior solid tumor	Treated at any time point in the patient's past history, excluding nonmelanoma skin cancer	3
Heart valve disease	Except mitral valve prolapse	3
Severe pulmonary	DLCO and/or FEV$_1$ ≤65% or dyspnea at rest or requiring oxygen	3
Moderate/severe hepatic	Liver cirrhosis, bilirubin > 1.5 × ULN, or AST/ALT > 2.5 × ULN	3

HCT-CI of 0 predicts for 2-year NRM of 14%
HCT-CI of 1–2 predicts for 2-year NRM of 21%
HCT-CI of ≥3 predicts for 2-year NRM of 41%

BOX 105.3 Refined Disease Risk Index

Refined DRI Category	Definition of Refined DRI Category	2-Year Overall Survival
Low	• Hodgkin lymphoma, mantle cell lymphoma, indolent non-Hodgkin lymphoma (NHL), chronic lymphocytic leukemia (CLL) or favorable-cytogenetics acute myeloid leukemia (AML) in complete remission (CR) • CLL or indolent NHL in partial remission (PR) • First or second chronic phase chronic myelogenous leukemia (CML)	66%
Intermediate	• CML advance phase • Mantle cell lymphoma, T-cell NHL, Hodgkin lymphoma, or aggressive NHL in PR • CLL or indolent NHL with stable or progressive disease • Acute lymphoblastic leukemia (ALL) in first CR • Intermediate-cytogenetics AML or aggressive NHL in CR • Myeloproliferative neoplasm • Low-risk myelodysplastic syndrome (MDS) with adverse-cytogenetic or high-risk MDS with intermediate-cytogenetics • Multiple myeloma in CR/very good PR/PR	51%
High	• T-cell NHL, Hodgkin lymphoma, mantle cell lymphoma, myeloma with stable or progressive disease • Burkitt lymphoma in CR • ALL in second or third CR • Adverse-cytogenetics AML in CR • Intermediate-cytogenetic AML with induction failure or active relapse • High-risk MDS with intermediate cytogenetics and advanced disease • Any-risk MDS with adverse cytogenetics and advanced disease	33%
Very High	• CML blast phase • Burkitt lymphoma in PR • Adverse-cytogenetic AML or ALL with induction failure or active relapse • Aggressive NHL with stable or progressive disease	23%

LONG-TERM SURVIVAL AFTER ALLOGENEIC TRANSPLANTATION

Most HCT-related deaths occur within the first 2 years. However, an analysis of 2 year survivors found that, compared with age- and nationality-matched death rates among the general population, subsequent survival was still inferior for HCT recipients.[92] Overall, 85% of 2-year survivors were still alive at 10 years post-HCT. Late relapse was the major cause of late deaths and was associated with advanced disease at HCT. Older age and GVHD were the other major predictors of late mortality.

The number of long-term HCT survivors is growing. Most 5-year survivors are well, off all immune suppression and leading normal lives. However, transplant recipients remain at risk for a variety of late complications, including late infections, cataracts, abnormalities of growth and development, thyroid disorders, chronic lung disease, osteoporosis, and avascular necrosis. There is also an increased incidence of leukemias, myelodysplasia, and solid tumors in transplant recipients, compared with the general population. Lifelong surveillance is necessary, as is increased awareness of late complications among the many non-transplant physicians who will care for these patients. Recommended long-term follow-up (LTFU) of HCT recipients is summarized in Box 105.4.[93] HCT-specific LTFU or survivorship clinics, though formally operational in less than half the North American transplant centers, are helpful in delivering individualized longitudinal survivorship care and transition of care from pediatric to adult setting. They also assist local physicians remote from the transplant center.[94]

DISEASE-SPECIFIC INDICATIONS FOR ALLOGENEIC TRANSPLANTATION

Acute Myeloid Leukemia

There is general agreement that most patients under the age of about 60 years who fail conventional therapy for AML and who possess good performance status are best treated with allogeneic transplantation if an appropriate related or unrelated donor is available. HCT is not recommended for those with favorable risk cytogenetics in CR1. The National Comprehensive Cancer Network (NCCN) guidelines, widely used to guide cancer therapy in the United States, distinguishes between AML patients ≤60 versus those greater than 60 years of age. Among younger patients, the panel recommended a post-remission strategy, based on factors such as the expected relapse rates with non-transplant therapy alone, salvage treatment options at relapse and patient-specific comorbidities that predict for NRM. The guidelines uniformly endorsed allogeneic HCT from related or unrelated donors, including cord blood HCT, in first CR for patients with unfavorable cytogenetic or molecular abnormalities, therapy-related AML, or prior myelodysplasia. Among those older than 60 years, the recommendation was to consider HCT as an early option in those achieving CR and as treatment for induction failure only in patients with low-volume residual disease. For relapsed AML, HCT was recommended irrespective of age but only after a second CR was achieved or in the context of a clinical trial. For patients with acute promyelocytic leukemia, the recommendation was to reserve allogeneic HCT for relapsed patients with persistent disease, despite salvage therapy.

The ASTCT guidelines for allogeneic HCT recently recommended HCT for AML patients in CR1, with intermediate-risk and high-risk disease and in the relapse setting (preferably after achievement of CR).[95] The European LeukemiaNet guidelines are in line with the ASTCT evidence-based policy and recommend allogeneic HCT for patients with intermediate-risk and adverse-risk cytogenetics in CR1, for patients with primary refractory disease, and for patients in CR2.[96] Patients in CR, but with persistent MRD or recurrent MRD, may proceed directly to HCT using MAC or may receive salvage therapy and proceed to HCT before relapse, depending on the likely efficacy of salvage therapy.

A systematic review of various national guidelines found the following:[97]

a. Consistent recommendations that patients with relapsed or refractory disease or high-risk cytogenetics be considered for HCT early;
b. Consistent recommendations that patients with good prognosis cytogenetics receive HCT only after failure of non-transplant therapy;
c. Inconsistent recommendations for patients with intermediate risk disease or without a family donor regarding transplantation in first remission.

Most national guidelines recommend a risk-based approach to guide selection of chemotherapy versus transplant approaches, using factors such as patient age, comorbid conditions, disease phenotype at diagnosis, and the number of cycles of therapy before achieving remission. MRD identified by multicolor flow cytometry,[98,99] real-time quantitative polymerase chain reaction,[100] and next-generation sequencing (NGS)[101] have been found to be an independent prognostic indicator in AML that is predictive of post-transplant outcomes in AML patients, and that pre-transplant MRD assessment by multi-color flow cytometry or molecular techniques can be used for risk stratification at the time of HCT.[102–106] A retrospective analysis of MRD and conditioning intensity was performed using pre-transplant samples from the phase III MAC versus RIC trial (BMT CTN 0901). Ultra-deep, DNA-based sequencing for 13 commonly mutated genes in AML was used for MRD detection.[107] Patients with no MRD had similar survival, regardless of conditioning intensity. In patients with detectable mutation, RIC (compared with MAC) was associated with higher relapse and lower relapse-free and overall survival, indicating that MAC can improve survival in MRD-positive AML patients in CR.

Acute Lymphoblastic Leukemia

Allogeneic HCT in first remission, from related or unrelated donors, is generally accepted as the most effective therapy for patients with Ph+ ALL. For adults with Ph-negative ALL (Ph− ALL), the appropriate timing of HCT is more controversial, despite the largest prospective study (Medical Research Council/Eastern Cooperative Oncology Group [MRC/ECOG]) and a meta-analysis suggesting a survival advantage for those assigned to transplant in CR1.[108,109] Another meta-analysis, limited to non-Ph+ ALL patients in CR, showed an overall survival benefit with allogeneic HCT, using a matched sibling donor for patients less than 35 years of age but not for older patients.[110] Allogeneic HCT is recommended in ASTCT guidelines for adult patients in CR2 and beyond and with high-risk ALL (including Ph+ ALL, t(4;11)) in CR1.[89] An evidence-based review and the most recent consensus recommendations from the ASTCT recommend allogeneic HCT for patients with standard-risk ALL in CR1, even while acknowledging the similar or superior outcomes with treatment on intensified pediatric-inspired protocols and without upfront allogeneic HCT in patients with no MRD.[111] Consolidation with allogeneic HCT should be considered after induction for patients with MRD, albeit after attempting to eliminate MRD with additional therapy. For example, treatment with blinatumomab to MRD negativity, before HCT, should be considered in B-ALL.[112] Among Ph+ ALL patients receiving HCT in CR1, conditioning intensity (RIC vs. MAC) did not influence outcomes before HCT for those without MRD, whereas those with residual MRD had inferior outcomes following RIC.[111] In the absence of randomized data against HCT, patients with high-risk ALL should still be considered for HCT even if they achieve MRD negativity.[111] For standard-risk adolescents and young adults (AYA) ALL patients with early MRD-negative CR1 status and pediatric-inspired regimens, continued chemotherapy consolidation and maintenance is recommended, while reserving allogeneic HCT for patients in CR2. For AYA patients with high-risk ALL and those with persistent MRD after induction, upfront allogeneic HCT consolidation should be

BOX 105.4 Recommended Practices for Allogeneic Transplant Recipients in Long-Term Follow-Up

	6 Months	12 Months	Annual	Comments (a)
Liver:				
Liver function tests	√	√	[a]	Annual check only if previously abnormal or new signs/ symptoms

considered. Post-transplant TKI for maintenance or as preemptive MRD-guided therapy should be considered in Ph+ ALL, despite the lack of high-quality prospective randomized data. A position statement from the Acute Leukemia Working Party of the EBMT and European Working Group for Adult Acute ALL also recommended allogeneic HCT for Ph- ALL with high-risk features, including MRD persistence ($<10^{-3}$ in marrow).[113] However, in Ph- ALL patients in CR1 with absence of MRD, continued intensified pediatric-inspired treatment, rather than upfront allogeneic HCT, is increasingly considered an acceptable strategy.[113] ALL patients who do not achieve MRD negativity after induction chemotherapy should be considered for allogeneic HCT,[79] acknowledging that their outcomes are likely inferior compared with patients undergoing HCT without evidence of MRD. Anti-CD19 CAR-T cell therapy has proven efficacy and shown impressive outcomes in patients with relapsed and refractory B-ALL: tisagenlecleucel (Kymriah, Novartis Pharmaceuticals Corp., Basel, Switzerland) and is approved by the US FDA for treatment of children and young adults up to 25 years of age, with second or later relapse and with refractory B-ALL.[114] Additional clinical data are required to determine the optimal utilization and sequencing of CAR-T-cell therapies in relation to allogeneic HCT, for instance, as a bridge to HCT, as definitive MRD-dictated intensification versus as treatment of ALL relapse post-HCT—current guidelines lack recommendations on these open questions.

Chronic Myelogenous Leukemia

In general, allogeneic HCT is indicated for patients whose initial presentation is in blast phase (BP) and should be considered for those with a suboptimal response or relapse while on TKIs.[115] HCT is also a consideration for patients who have *BCR-ABL* mutations that predict for TKI non-response (e.g., *T315I* mutation). It is important to establish a monitoring plan for early signs of progression and for mutation screening, since outcomes are significantly better if HCT is performed before transformation to an advanced disease stage. Definitions of suboptimal response and failure with TKIs and guidelines for monitoring have been developed.[116,117] European LeukemiaNet guidelines have addressed timing of allogeneic HCT in CML.[117] Allogeneic HCT is recommended in CML patients presenting in or progressing to BP, for patients progressing to accelerated phase (AP) during treatment, and patients presenting with AP who have suboptimal response to TKIs. For patients in AP and BP, allogeneic HCT should be offered after achieving disease control, since patients in second chronic phase (CP) before HCT have improved outcomes.[118] For patients in CP, a CIBMTR registry study showed a 5-year OS of 75% in early chronic phase CML, making it a potential curative clinical option in this subset of patients under special circumstances. We consider allogeneic HCT for those who are refractory or intolerant to at least one second-generation TKI in first- or second-line therapy, and in patients with T315I mutation, especially in those with suboptimal response to ponatinib.[89] A registry-based, retrospective comparison of myeloablative versus RIC and non-myeloablative conditioning in CML patients up to 60 years of age revealed similar survival, despite higher relapse risk with non-MAC regimens.[119]

Chronic Lymphocytic Leukemia

The introduction of signaling pathway inhibitors, such as Bruton tyrosine kinase inhibitor (BTKi; ibrutinib), phosphatidylinositol-3-kinase inhibitor (PI3Ki; idelalisib), and BCL2-inhibitor (BCL2i; venetoclax) has altered the position of HCT in the chronic lymphocytic leukemia (CLL) treatment algorithm. Recent EBMT consensus is that patients with chemoimmunotherapy-resistant CLL, with *TP53* abnormalities, but responsive to a first pathway inhibitor (BTKi or BCL2i), could be offered allogeneic HCT if deemed low risk for NRM, even though most of these patients could continue to be treated with pathway inhibitors.[115,120] CLL patients with resistance to both chemoimmunotherapy and at least one pathway inhibitor should be considered for allogeneic HCT, even if responding to an alternate pathway inhibitor. These recommendations supplant ASTCT Practice Guidelines that favor allogeneic HCT for relapsed/refractory CLL patients, with del(17p) and/or *TP53* mutations, with or without complex karyotype, regardless of sensitivity to pathway inhibitors (responsive or refractory to BTKi and/or BCL-2i).[121] In addition, allogeneic HCT is a strong consideration for CLL patients developing Richter transformation, after achieving a response to anthracycline-based chemotherapy.[121] HCT and pathway inhibitor drugs are not mutually exclusive in the CLL landscape: both have a role in the management of CLL, which continues to evolve.[120] With the potentially complementary effects of pathway inhibitors and allogeneic HCT (graft-versus-leukemia effect), strategic and non-competitive employment of pathway inhibitors before and/or after HCT will likely synergistically improve outcomes in patients with high-risk CLL. CAR-T-cell therapy, targeted at CD 19, has been in clinical trials for CLL and once mature data are available, the position and timing of allogeneic HCT would require a reappraisal.

Diffuse Large B-Cell Lymphoma

Allogeneic HCT role in diffuse large B-cell lymphoma (DLBCL) has undergone recent evolution with the availability of CAR-T-cell therapy. A decline in the number of autologous HCT for DLBCL was noted in 2018 compared with previous years,[4] following the approval of CD19-directed CAR-T cells in 2017 (axicabtagene ciloleucel, Yescarta) (Kite Pharma, A Gilead Company, Los Angeles, CA); tisagenlecleucel, Kymriah (Novartis Pharmaceuticals Corp., Basel, Switzerland) is used for treatment of DLBCL patients failing at least two lines of therapy, with or without autologous HCT.[122–124] Notably, an EBMT report recommended allogeneic HCT as the established standard for chemosensitive relapse, after failure of a prior autologous HCT.[115] Understandably, in the absence of comparative studies there is growing uncertainty regarding the role of allogeneic HCT in DLBCL management. In the United States, CAR-T cell therapy has rapidly become the preferred option for relapsed/refractory DLBCL as a result of its safety and efficacy in refractory disease, while allogeneic HCT appears to be positioned as treatment of post-CAR-T relapses.[125,126] A few exceptions include relapsed DLBCL patients with refractory cytopenias and therapy-related myelodysplastic syndrome, which are indications to be considered for allogeneic HCT rather than CAR-T therapy.[125] A collaborative registry-based (EBMT and CIBMTR) analysis compared outcomes of RIC allogeneic HCT for relapsed DLBCL, using the three major donor types: haploidentical donor grafts using post-transplant CY, matched sibling donor, or matched unrelated donor.[49] No differences in NRM, relapse, or overall survival between haploidentical and matched donor HCT were observed. A 3-year OS of 46 and PFS of 38% underscored the promise of allogeneic HCT to rescue DLBCL patients.

Follicular Lymphoma

The vast majority of relapsed, chemotherapy-sensitive FL patients can experience durable disease control with autologous HCT. Allogeneic HCT can be considered after autologous HCT failure, and in those who have heavily pretreated disease, persistent marrow involvement, or chemo-unresponsive (but relatively low bulk disease). In the allogeneic setting, RIC is the standard of care, with limited role for MAC regimens.[127] The recent ASTCT guidelines added a category of patients with follicular lymphoma with early treatment failure, defined as a lack of response or relapse/progression within 2 years of frontline chemoimmunotherapy.[89] Registry-based analyses suggest efficacy of autologous HCT (with low NRM) and allogeneic HCT from a matched sibling donor (with low relapse rate), resulting in improved overall survival in this high-risk subset of follicular lymphoma patients.[128,129] CAR-T-cell therapies (axicabtagene ciloleucel or tisagenlecleucel) have emerged as an effective salvage option for patients who have failed ≥2 prior chemoimmunotherapy regimens for transformed follicular lymphoma, who may or may not be eligible for HCT.[124] CAR-T-cell therapies for B-cell malignancies are expected to impact the role of allogeneic HCT for relapsed FL in the near future.

Mantle Cell Lymphoma

NCCN guidelines recommend autologous transplantation as an adjunct to initial therapy in eligible patients.[124,130] Expert consensus opinion is that allogeneic HCT has a limited role as upfront consolidation in chemotherapy-sensitive disease.[89,115] Given the poor prognosis of relapsed mantle cell lymphoma and the curative potential of allogeneic HCT, it is a reasonable option for patients relapsing after upfront autologous transplantation or those with BTKi-refractory disease. KTE-X19, an anti-CD19 CAR T-cell therapy, was evaluated in a single-arm phase II trial for relapsed/refractory mantle cell lymphoma patients, progressing on or after BTKi therapy and resulted in durable remissions in a majority of patients.[131] The recent approval of KTE-X19, now known as brexucabtagene autoleucel, may augur changes in the utilization and timing of allogeneic HCT in mantle cell lymphoma.

T-Cell Lymphoma

ASTCT and NCCN guidelines recommend consideration of allogeneic HCT in the relapsed or refractory setting in T-cell lymphoma.[89,124,132] Autologous HCT is recommended as front-line consolidation in and for relapsed-sensitive T-cell lymphoma subtypes, including peripheral T-cell lymphoma-not otherwise specified (PTCL-NOS), angioimmunoblastic T-cell lymphoma (AITL), anaplastic large-cell lymphoma, anaplastic lymphoma kinase (ALCL-ALK)-negative, natural killer (NK)/T-cell (disseminated), and hepatosplenic lymphoma, despite the lack of randomized evidence.[133–135]. Autologous HCT is recommended for relapsed-sensitive ALCL-ALK-positive, where it is not offered in front-line consolidation.[133] Allogeneic HCT is strongly recommended (based on retrospective and registry data) for high-risk histologies and in settings where chemotherapy-based approaches are non-curative (e.g., front line in adult T-cell leukemia/lymphoma) (ATLL; acute and lymphoma type), hepatosplenic lymphoma, NK cell leukemia, and for chemotherapy sensitive relapse of NK/T-cell (disseminated), mycosis fungoides/Sezary syndrome (advanced stage); and for relapse post autologous transplant in subtypes that are typically offered autologous HCT in the first-line (PTCL-NOS, AITL, ALCL-ALK-negative).[136–144]

Hodgkin Lymphoma

With the recent approval of three novel agents (brentuximab vedotin,[145] and checkpoint inhibitors, nivolumab[146] and pembrolizumab[147]), allogeneic HCT is currently recommended only for Hodgkin lymphoma patients, relapsing after a prior autologous HCT and after brentuximab vedotin failure.[89,148,149] In high-risk Hodgkin lymphoma (with a median age in the early 30 s in most published data), patients who have progressed after autologous HCT and brentuximab vedotin, checkpoint inhibitors result in modest response with suboptimal durability.[146,147] Such patients have improved survival outcomes with allogeneic HCT, and a CIBMTR analysis suggested that the haploidentical-related donor HCT with post-transplant CY (vs. matched sibling donor HCT) resulted in lower relapse and comparable survival in relapsed Hodgkin lymphoma patients.[50] NCCN guidelines currently consider allogeneic HCT in progressive or relapsed Hodgkin lymphoma as a category 3 recommendation (major disagreement).[150]

Allogeneic HCT is a frequently considered treatment option in heavily pretreated HL patients, including those relapsing.

Multiple Myeloma

First-line autologous HCT continues to be the standard of care for newly diagnosed myeloma patients, which in turn remains the most common indication for autologous HCT.[4,151,152] Allogeneic HCT with RIC has been studied in randomized studies, comparing it in the tandem auto-allo HCT fashion versus tandem autologous transplantation.[153–155] Results have been disparate with the large US-based BMT CTN 0102 study failing to show a PFS or OS advantage for allogeneic HCT, while a similar EBMT study did show a long-term survival and PFS advantage. A long-term follow-up study, using a large pooled dataset of four prospective trials with biological randomization between tandem autologous HCT and autologous-allogeneic HCT, showed significantly improved OS, as well as PFS and post-relapse survival in favor of allogeneic HCT.[156] Given the significant expansion in myeloma therapeutics, the use of upfront allogeneic HCT has declined.[4] Allogeneic HCT has been considered for ultra-high-risk myeloma in clinical trials (BMT CTN 1302), but an optimal patient population is still not uniformly agreed upon. ASTCT guidelines do not recommend routine upfront myeloablative allogeneic HCT, nor planned tandem autologous-RIC allogeneic HCT.[157] However these guidelines support allogeneic HCT in myeloma in the context of a clinical trials or in clear high-risk disease, such as plasma cell leukemia. Prospective trial data on allogeneic HCT for relapsed myeloma are sparse; a CIBMTR analysis suggested no survival advantage in favor of salvage allogeneic HCT, over autologous HCT in relapse setting.[158] Several post-relapse survival comparisons of patients relapsing after allogeneic HCT versus single or tandem autologous HCT have shown post-relapse survival advantage in allogeneic HCT recipients.[155,159,160]

CHAPTER 106

UNRELATED DONOR HEMATOPOIETIC CELL TRANSPLANTATION

Effie Wang Petersdorf and Katharine Hsu

The outcomes of unrelated donor hematopoietic cell transplantation (HCT) have greatly improved as a result of a better understanding of the diversity of human leukocyte antigen (HLA) and killer-cell immunoglobulin-like receptor (KIR) genes. The HLA and KIR genetic systems regulate the transplantation barrier. Clinical outcomes after unrelated donor transplantation can be achieved with donor matching for the highly polymorphic HLA loci and through consideration of donor KIR genes. When HLA disparity cannot be avoided, judicious selection of a donor with the fewest HLA mismatches and avoidance of certain loci may provide patients with the opportunity for life-saving transplantation. The disease stage remains a strong predictor of overall transplant outcome, and expediency in timing of transplantation for patients with high-risk disease is paramount. New research avenues include the identification of major histocompatibility complex (MHC) and KIR genetic variation that may contribute to risks of graft-versus-host disease (GVHD) and relapse. This chapter chronicles the role of HLA and KIR genes in unrelated donor HCT.

THE HUMAN LEUKOCYTE ANTIGEN AND KILLER-CELL IMMUNOGLOBULIN-LIKE RECEPTOR GENETIC SYSTEMS

Genetics of the Human Leukocyte Antigen Complex

The advent of molecular techniques has made possible the definition of unique sequence variants (alleles) of HLA molecules that are recognized by an antibody (Table 106.1). Polymorphism ensures that a large array of foreign peptides can be presented to the immune system by HLA molecules. As of May 2020, a total of 26,887 alleles are recognized.[1] HLA nomenclature accommodates the steady discovery of new human variants and has no limits on the number of novel variants. The HLA prefix is followed by a hyphen and the gene name (e.g., HLA-A). An asterisk separates the gene from the unique sequence (HLA-A*). The unique sequence name embodies up to four kinds of information, each delimited by a colon. The first set of numbers after the asterisk and before the first colon correspond to the serologic antigen equivalent (e.g., HLA-A*02 refers to sequences of the HLA-A2 antigen family). The second set of numbers provides the unique protein that corresponds to the subtype (HLA-A*02:101). The third set of numbers indicates synonymous substitutions (HLA-A*02:101:01). The last series of numbers give information on noncoding variation often denoting expression (HLA-A*02:101:01:02 N). Letter suffixes are used to denote alleles that are not expressed (also known as "null," N), low cell surface expression (L), a soluble secreted molecule not present on the surface of the cell (S), a cytoplasmic product not expressed on the cell surface (C), a protein with aberrant expression (A), and a sequence of questionable expression (Q).

If HLA alleles can be expressed in any combination and if the inheritance of alleles were random, then the total estimated number of possible five-locus HLA-A, HLA-B, HLA-C, HLA-DRB1, and HLA-DQB1 genotypes would be exceedingly high, and the chances of identifying a fully matched donor would be very low. Clinical experience demonstrates that donor identification is successful and is due to the underlying genetic hallmark of the MHC, linkage disequilibrium (LD). LD refers to the observation that HLA alleles are found in association with each other at an observed frequency that exceeds their expected frequency. The probability of identifying a matched donor for a given patient is higher when the patient and donor share a similar ethnic background. HLA gene and haplotype frequencies provide important data for estimating optimal registry size and composition.[2] Given the polymorphism of allele sequences that encompass variants of a single serologically defined antigen, it is not surprising that antigen-matched donor and patient pairs may differ by their alleles.

HUMAN LEUKOCYTE ANTIGEN TYPING METHODS

The development of standardized typing methods and nomenclature for HLA genes have been facilitated by a series of 17 international histocompatibility workshops (Table 106.2). The terms "low-resolution," "intermediate-resolution", and "high-resolution" are a reflection of the evolution of DNA methods and their equivalency to serologically defined specificities. The term "6/6" match refers to recipients and donors who share the same low-resolution-defined HLA-A, HLA-B, and HLA-DR genes. The term "8/8" refers to high-resolution matching at the four loci HLA-A, HLA-B, HLA-C, and HLA-DRB1; "10/10" to the addition of HLA-DQB1, and "12/12" to the addition of HLA-DPB1.

Next-generation sequencing (NGS) platforms are the most current sequencing methodology which provide not only "ultra-high resolution" of HLA alleles (typing of the gene beyond its coding regions) but also short-range phasing of exons 2, 3, and 4 of class I genes, and of exons 2 and 3 of class II genes.[3,4] NGS has the capability of linking sequences across exons that substantially reduces ambiguities of allele combinations.[5,6] NGS approaches for HLA typing are supported by software for automated allele assignment. Because many samples may be tested simultaneously, NGS is a cost-effective typing method for typing donors recruited into registries.[4]

GENETICS OF THE KILLER-CELL IMMUNOGLOBULIN-LIKE RECEPTORS SYSTEM

Recognition that natural killer (NK) cells engage HLA, leading to the capacity to discern self from non-self, has generated interest in the NK receptors responsible for HLA binding (Table 106.3). Located on chromosome 19, the KIR gene region is similar to the HLA gene complex in that it is also polygenic and polymorphic; however, unlike the HLA genes, whose loci are conserved across all individuals, KIR genes frequently differ from individual to individual. As few as eight and as many as 14 different KIR genes and pseudogenes may be found on one haplotype, with some genes existing more than once.[7] KIR genes encode two broad categories of receptors: mmunoreceptor tyrosine-based inhibition motif (ITIM)-containing inhibitory receptors and mmunoreceptor tyrosine-based activation motif (ITAM)-binding activating receptors. Nomenclature for the KIR genes is structurally inspired: the first two characters (2D or 3D) refer to the number of extracellular Ig-like domains characterizing the receptor; the third character (L or S) refers to the "long" inhibitory or "short" activating cytoplasmic tail of the receptor, and the last character (numbering 1 through 5) differentiates receptors with similar numbers of extracellular domains and cytoplasmic tail length. The inhibitory receptors

TABLE 106.1 Common Definitions in Human Leukocyte Antigen and Killer-Cell Immunoglobulin-Like Receptor Genetics

Term	Definition	Example
Allele	Unique sequence of an HLA gene defined by molecular methods	DRB1*04:01 allele is a unique sequence defined as DR4 by serologic methods
Antigen	Antibody-defined protein	DR4 antigen is a serologically defined protein product of an HLA gene
Antigen matched	HLA-B*44	HLA-B*44
Antigen mismatched	HLA-B*44	HLA-B*27
Antigen matched and allele matched	HLA-B*44:02	HLA-B*44:02
Antigen matched but allele mismatched	HLA-B*44:03	HLA-B*44:02
HLA haplotype	HLA genes inherited as a chromosomal unit	HLA-A1, HLA-B8, HLA-DR3 are common haplotypes among White populations
HLA genotype	Molecularly defined HLA allele or sequence	Genotypically matched donor and recipient are identical for the HLA alleles at a given HLA gene (e.g., HLA-DRB1*04:01)
HLA phenotype	Serologically defined HLA protein or antigen	Phenotypically matched donor and recipient share the same HLA antigen (e.g., HLA-DR4)
KIR haplotype	KIR genes inherited as a chromosomal unit	KIR2DL3, KIR2DL1, KIR3DL1, and KIR2DS4 are present together on a common haplotype
KIR genotype	Repertoire of KIR genes present in an individual	
KIR phenotype	Cell surface expression of KIR receptors within the NK population, both at the level of frequency of expression and density of expression	KIR2DL1 alleles are expressed at different frequencies within the NK population and at different cell surface densities on an individual NK cell
KIR ligand	Molecule binding the KIR receptor	HLA alleles belonging to the HLA-Bw4, HLA-C1, and HLA-C2 groups
KIR ligand incompatibility	Dissimilar KIR ligands in the HCT recipient and donor	Donor has HLA-Bw4, C1, and C2 KIR ligands, but the recipient has HLA-C1 only
Missing self	HCT recipient lacking KIR ligand present in the donor.	Donor has HLA-Bw4, C1, and C2 KIR ligands, but recipient lacks HLA-C2
Missing KIR ligand	Individual having the inhibitory KIR receptor without the ligand	Individual is positive for KIR2DL1 but negative for HLA-C2
NK education	Capacity for effector response against missing self. Dictated by interaction between inhibitory KIR and its ligand.	NK cells expressing KIR3DL1 in an HLA-Bw4+ individual are educated for response.

HLA, Human leukocyte antigen; *KIR*, killer-cell immunoglobulin-like receptor; *NK*, natural killer.

recognize HLA class I ligands, and interaction between the receptor and its cognate HLA ligand is responsible for establishing the response threshold upon encountering a putative target. It is in this way that a KIR-expressing NK cell becomes educated to behave indifferently toward cells bearing self-HLA ligands and aggressively toward cells that have lost or altered HLA expression.

The KIR genes are arranged neatly in a head-to-tail manner within a highly organized cluster with prototypic gene order, leading to LD between pairs and clusters of KIR genes and alleles.[7–9] The so-called anchor genes and pseudogenes, recognized for their distinctive positions on nearly all identified KIR haplotypes, demarcate the beginning, middle and end of the KIR gene cluster. KIR3DL3 and KIR3DL2 flank the KIR genetic region, while KIR3DP marks the end of the centromeric portion and KIR2DL4 marks the beginning of the telomeric portion of the haplotype.[7,10,11] The centromeric and telomeric portions appear to have evolved and diversified separately due to reproductive and pathogenic pressures,[12] and the gene content distinctive to each region may have clinical relevance in HCT.[13]

Population studies of KIR genotypes identified the presence of two major KIR haplotype groups, the A-haplotype and the B-haplotype,[10,11] where, apart from the anchor genes, the canonical A-haplotype is comprised of the genes KIR2DL3, -2DL1, -3DL1, and -2DS4. By contrast, B haplotypes are more variable in gene content, exhibiting more than one activating KIR gene—KIR2DS1, KIR2DS2, KIR2DS3, KIR2DS4, KIR2DS5, and KIR3DS1—in the centromeric and/or telomeric regions.[14]

Allelic polymorphism of each KIR locus lends additional diversity to the genetic region, with new alleles reported regularly.[15] The loci encoding inhibitory KIR receptors are the most diverse, with 183 KIR3DL1, 165 KIR3DL3, 164 KIR3DL2, 111 KIR2DL1, 64 KIR2DL3, and 34 KIR2DL2 alleles reported as of March 2020. KIR allele sequences are named in an analogous fashion to HLA.[16] An asterisk separates the KIR gene name (e.g., KIR2DL1) from the numeric allele sequence (KIR2DL1*). The first three digits following the asterisk indicate alleles that encode different protein sequences (KIR2DL1*003), followed by two digits that distinguish alleles whose DNA differences within the coding sequence are synonymous (KIR2DL1*00302). The last 2-digit field identifies alleles that differ by DNA substitutions in non-coding regions (KIR2DL1*0030202). For some KIR loci (e.g., KIR3DL1 and KIR2DL1), alleles can be grouped into subtypes based on shared sequences that distinguish them based on cell surface expression or function.[17–19]

TABLE 106.3 Donor Killer-Cell Immunoglobulin-Like Receptor Models

		Examples	
Definition	**Donor-Recipient HLA Match**	**Donor**	**Recipient**
Missing self	Mismatched	KIR3DL1 + HLA-Bw4	Lacking HLA-Bw4
Missing ligand	Matched or mismatched	KIR2DL1 + HLA-C1/C1	HLA-C1/C1(missing HLA-C2)
KIR haplotype-B	N/A	KIR haplotype-B members (activating KIR-rich)	N/A
KIR2DS1 + HLA-C1	Matched	KIR2DS1 + HLA-C1	HLA-C1
KIR3DL1 inhibition	Matched	KIR3DL1-H + HLA-Bw4-80T	HLA-Bw4-80T

HLA, Human leukocyte antigen; *KIR*, killer-cell immunoglobulin-like receptor.

KILLER-CELL IMMUNOGLOBULIN-LIKE RECEPTORS TYPING METHODS

Identification of KIR genotypes can be performed at the resolution of the KIR gene, subtype, and allele by a number of different molecular approaches. Currently, polymerase chain reaction (PCR) sequence-specific primers (SSP) and sequence-specific oligonucleotide probes (SSOP) are employed by clinical laboratories for KIR gene content. For research purposes, PCR-SSP is used to identify subtypes and some alleles.[8,20,21] Whole-genome sequencing and RNA-seq databases are rich resources for algorithmic extraction of KIR gene content and copy number.[22,23] More recently, NGS has emerged as a powerful research tool for KIR gene and allele discrimination, with the anticipation of more widespread use as evidence for the clinical importance of KIR genotyping increases.[24]

DONOR IDENTIFICATION AND LIKELIHOOD OF TRANSPLANTATION

The field of unrelated donor HCT has witnessed rapid growth over the past 30 years. Among all allogeneic transplantations performed in the US, the number of transplants from unrelated donors exceeds that from related donors since 2006.[25] The primary indications for unrelated donor HCT are acute myeloid leukemia (AML), myelodysplastic syndrome/myeloproliferative disorders (MDS/MPD), acute lymphoblastic leukemia (ALL), non-Hodgkin lymphoma (NHL), and other nonmalignant disorders. Starting in 2005, patients between 60 and 69 years of age comprised the fastest-growing group of transplant recipients as a result of the introduction of non-myeloablative and reduced-intensity conditioning regimens. Since 2011, patients at the age of 70 or older are the fastest-growing group of allogeneic transplant recipients.

Unrelated HCT has been made feasible by the establishment of registries of volunteer donors worldwide. The Anthony Nolan Appeal was the first effort to demonstrate the feasibility of donor recruitment. Now known as the Anthony Nolan Research Institute, this registry was the first to promote access to HLA-matched bone marrow (BM) donors for patients around the world. In the United States, early efforts for donor recruitment were spearheaded by individual centers. The growing interest in unrelated donor HCT led the US Congress to authorize the creation of a national registry comprising a network of donor centers, transplant centers, and a national coordinating center through the Transplant Act of 1984. Two years later, a federal contract to establish a national registry was awarded to the National Marrow Donor Program (NMDP). In the Netherlands, Professor Jon J. van Rood led the Europdonor Foundation in the collection of HLA data from donor registries around the world and the formation of a database of HLA phenotypes known as Bone Marrow Donors Worldwide (BMDW).[25] Continued growth in registry size worldwide has increased the chances that well-matched donors can be identified. Today, more than 37 million donors are available through international cooperative agreements with registries around the world.[25] The likelihood of identifying an HLA-A, -B, -C, -DRB1-matched (HLA-8/8) unrelated donor depends on the patient's race and ethnicity, with higher rates in patients of White European descent than other ethnicities. In the Japanese population, the probability of identifying an HLA-8/8 match increases as registry size increases but is predicted to reach a limit due to population-specific allele and haplotype frequencies.[26] Strategies to estimate the likelihood of any given patient's success in identifying HLA-matched donors take into account the patient's race and ethnicity. When criteria are relaxed to permit mismatching, over 98% of patients of European descent and over 80% of patients of non-European origin have HLA-7/8 donors.[27] Use of cord blood can further extend access to transplantation.[28]

The identification of HLA-matched donors is only one potential barrier to transplantation for patients. Donor availability, donor health issues, donor race, delays due to coordination, and deterioration of patient health may also lower the chances that a patient can undergo transplantation (Box 106.1).[29] Identification of primary and backup donors allows patients to reach transplantation and improves the overall survival of patients with good performance status, compared to not having a suitable donor.[30]

HUMAN LEUKOCYTE ANTIGEN CRITERIA

Selection of unrelated donors includes consideration for the degree of HLA matching and the presence of recipient anti-donor HLA antibodies, which place the patient at high risk for non-engraftment in the setting of HLA mismatching.[31] Evaluation of unrelated donors includes a health screening history, physical examination, and laboratory testing for risks associated with transmissible elements with a special focus on hepatitis B, hepatitis C, human immunodeficiency virus (HIV 1 and 2), human T-cell lymphotrophic virus I and II, malaria, West Nile virus, transmissible spongiform encephalitis (Creutzfeldt-Jacob disease), Chagas disease, *Treponema pallidum*, and cytomegalovirus (CMV).[32] This core screening is supplemented with an infectious disease health questionnaire screening with novel epidemics including Zika risk areas and COVID-19 exposure.[25] Increased awareness for the health and safety of the unrelated donor has led to the establishment of standards for donation.[25,33]

A large-scale registry study demonstrates that donor HLA match status and donor age are the two most important determinants of transplant survivorship.[34] Two-year survival was 3% better when a donor 10 years or younger is selected. These data demonstrate that transplant centers have the flexibility in donor selection, with the prioritization of HLA-matched young donors where possible (see Box 106.1).

HUMAN LEUKOCYTE ANTIGEN VECTOR OF MISMATCHING

The "vector" or "direction" of HLA compatibility between a donor and a recipient has biologic relevance in risks of graft failure and GVHD and applies to all classical HLA loci. The presence of donor

BOX 106.1 Clinical Relevance to Reaching Transplantation from the Initiation of an Unrelated Donor Search: Patient and Donor Factors[a]

Outcome	Patient Factors	Donor Factors
Probability of the patient reaching transplantation	Increased age[a]	HLA-A, B, C, DRB1, DQB1, DPB1 match status[b]
	Advanced disease risk/urgency of HCT[c]	Availability of high-resolution typing at search
Probability of patient survival	Karnofsky Performance Status (KPS)[a]	Availability/attrition[d]
		Increased age

[a] Pidala J, Kim J, Schell M, et al. Race/ethnicity affects the probability of finding an HLA-A, -B, -C and -DRB1 allele-matched unrelated donor and likelihood of subsequent transplant utilization. *Bone Marrow Transplant.* 2013;48:346–350.

[b] Donor HLA matching remains the most significant risk factor for transplant outcomes.

[c] Disease risk as categorized by the Center for International Blood and Marrow Transplantation Research (CIBMTR).

[d] Identifying the primary donor with a back-up will give flexibility in the scheduling of a transplant.

After the initiation of a search for an unrelated donor, older patients with more advance disease and no HLA-matched donor are associated with lower odds of reaching transplantation. Patients whose Karnofsky Performance Status is 90% to 100% and who have an available donor have significantly reduced hazard of death.[a]

alleles not shared by the recipient determines HVG allorecognition; the presence of recipient alleles not shared by the donor provides the immunologic basis for GVH allorecognition (Table 106.4). "Bidirectional" mismatching occurs when both HVG and GVH vectors are present at a given HLA locus. A recent analysis of the vector of mismatching confirms that outcome is associated with a GVH vector mismatch, and not when a GVH mismatch is absent.[35]

HUMAN LEUKOCYTE ANTIGEN HAPLOTYPES

Patients undergo a family study to determine the availability of potential HLA genotypically identical siblings who could serve as a donor (Box 106.2). HLA genes segregate in classical Mendelian fashion and there is a 25% probability that a sibling inherits the same parental haplotypes (genotypically identical), a 50% probability that a sibling shares one parental haplotype (haploidentical), and a 25% chance that the sibling is completely mismatched.

When no related donor is available or suitable, a search for an unrelated donor is initiated. A search of all available international registries today includes consideration of more than 37 million donors worldwide.[25,32] Unrelated donors are assessed for allele matching at each HLA locus. However, gene-by-gene identity for HLA-A, HLA-B, HLA-C, HLA-DR, and HLA-DQ between two unrelated individuals does not necessarily guarantee the HLA alleles are linked on the same chromosomal haplotype. HLA-matched transplants whose alleles are physically linked on the same extended haplotypes have lower GVHD than HLA-matched transplants whose alleles are encoded on different haplotypes.[36] In an independent study, the inferred phases of HLA-10/10-matched unrelated transplants based on haplotype frequencies did not correlate with the outcome.[37] Sequence-defined haplotypes in Japanese patients are themselves associated with the outcome.[38]

DONOR KILLER-CELL IMMUNOGLOBULIN-LIKE RECEPTOR CRITERIA

Consideration of donor KIR genotype differs significantly from HLA in that there is no conclusive evidence that matching for KIR genotype between donors and recipients has significant relevance to the clinical outcome of overall survival.[39–41] This is not surprising, given their differing contributions to immunity, where HLA is present on the target cell, while KIR resides on the effector cell. Unlike HLA, therefore, there is no negative consequence to the KIR gene or allele mismatching between HCT donor and recipient, as the KIR protein itself does not appear to be immunogenic. Nevertheless, consideration of donor KIR has a role in allogeneic HCT, but an understanding of how the interaction between KIR and HLA impacts NK biology is vital to the successful implementation of KIR assessment for donor selection in HCT.

NK cell response, its likelihood as well as its amplitude, is governed by the interaction between inhibitory receptors and environmental HLA ligands via an incompletely understood process referred to as "NK education."[42] Inhibitory KIR contributing to NK education include KIR3DL1, which recognizes the HLA-Bw4 epitope present on some HLA-A and -B allotypes; KIR2DL2 and KIR2DL3, which recognize HLA-C molecules characterized by Ser77,Asn80 (collectively referred to as HLA-C group 1); and KIR2DL1, which recognizes HLA-C molecules characterized Asn77,Lys80 (collectively referred to as HLA-C group 2). Although KIR3DL2 binds HLA-A*03 and -A*11, the binding appears to be peptide-dependent, and the receptor-ligand relationship does not appear to contribute to NK

BOX 106.2 PRINCIPLES OF HUMAN LEUKOCYTE ANTIGEN MATCHING AND DONOR SELECTION

Establish the Patient's Haplotypes

When an allogeneic transplant is being considered a part of the treatment regime for a patient, human leukocyte antigen (HLA) typing of the patient and first-degree relatives is performed early in the planning process to identify suitable related donors. Typing of family members provides 2 key pieces of information: (1) the availability of an HLA genotypically matched sibling or a suitable haploidentical related donor, and (2) confirmation of the patient's HLA tissue type. When both parents of the patient are available for tissue typing, the family study allows confirmation of the paternal and maternal HLA haplotypes, and this information is invaluable for predicting the probability of finding unrelated donors. In the absence of parents, tissue typing of available siblings might yield sufficient information for the four parental haplotypes.

Characterize Human Leukocyte Antigens at High Resolution

DNA-based methods are the mainstay for tissue typing. Molecular methods provide information of allelic variants at HLA-A, -B, -C, -DRB1, -DQB1, and -DPB1 that have been shown to have biological implications in graft-versus-host and host-versus-graft allorecognition. When a search for an unrelated donor yields potential registry donors that lack high-resolution typing, often knowledge of the patient's haplotypes may help to direct typing of donors that have the highest probability of matching the patient's alleles.

Determine the Presence of Anti-Donor Antibodies Against Mismatched HLA Proteins

The risk of graft failure is significantly increased when the patient has mounted an anti-HLA response against donor mismatched antigens. Screening donors with patient sera especially when the donor has known HLA mismatches, is an essential step of donor selection. When no HLA-matched donors are available, avoiding the use of donors whose HLA mismatches are the same specificity as the anti-HLA antibodies in the patient, may reduce the risk of graft failure.

Identify Back-up Donors

The efficiency of the unrelated donor search process is highly dependent on the racial and ethnic background of the recipient and the composition of the donor registries. The availability of unrelated donors must also factor into the planning of the transplant, including the identification of a primary donor and backup donors.

TABLE 106.4 Vector of Human Leukocyte Antigen Mismatch

Vector	Definition	Examples	
		Donor	Recipient
HVG	Presence of donor alleles not present in the recipient	DRB1*01:01,04:01[a]	DRB1*01:01,04:10
		DRB1*01:01,04:01[b]	DRB1*01:01,01:01
GVH	Presence of recipient alleles not present in the donor	DRB1*01:01,04:01[a]	DRB1*01:01,04:10
		DRB1*01:01,01:01[b]	DRB1*01:01,04:10

[a] These combinations contain bidirectional (both HVG and GVHD) mismatch vectors.
[b] Unidirectional mismatches.
GVH, Graft versus host; *HVG*, host versus graft.

education.[43,44] Because the HLA and KIR regions exist on separate chromosomes and are inherited in classic Mendelian fashion, it is common that an individual inherits KIR genes for which it lacks the encoded HLA ligand and vice versa. Expression of the KIR receptors is largely stochastic, leading to a repertoire containing NK cells that express inhibitory KIR for self-HLA and NK cells that express inhibitory KIR for which the HLA ligand may not be present. Tolerance to self is achieved via inhibitory signaling that occurs upon engagement of the KIR-bearing NK cell with cognate (self) HLA ligand on autologous neighboring cells. The same interaction leads to the differential acquisition of responsiveness, such that only NK cells exhibiting inhibitory receptors for self-HLA ligands have high response capacity and are "educated" for a response when confronted with a target cell lacking self-HLA ligand ("missing self").[45] In contrast, NK cells lacking inhibitory receptors for self-HLA, including NK cells expressing inhibitory receptors for non-self HLA (e.g., "missing ligand"), are "uneducated" and hyporesponsive. Both educated and uneducated NK cells play a role in allogeneic HCT.

The majority of activating KIR receptors do not recognize HLA molecules as a ligand themselves and, instead, bind a variety of viral epitopes.[46,47] The one exception is KIR2DS1, which signals NK activation upon engagement of the HLA-C2 ligand. Interestingly, KIR2DS1 also participates in NK education, tolerizing the NK cell based on the environmental "dosage" of HLA-C2, leading to hyporesponsive KIR2DS1$^+$ cells in individuals homozygous for HLA-C2 ligands.[19,48,49]

CLINICAL SIGNIFICANCE OF HUMAN LEUKOCYTE ANTIGEN AND KILLER-CELL IMMUNOGLOBULIN-LIKE RECEPTOR IN TRANSPLANTATION

Human Leukocyte Antigen Matched Transplantation

The impact of more complete and precise donor HLA matching is dramatic. Overall survival after transplantation for the treatment of AML, MDS, ALL, and CML from an HLA-8/8-matched unrelated donor can approach the results observed after HLA-identical sibling transplantation.[32] For all modalities, the underlying disease diagnosis and stage of disease at transplantation remain the most important prognostic features that affect disease-free survival (DFS). The general rules for donor HLA matching are applicable to different graft sources (BM or peripheral blood stem cells) and to different intensities of the conditioning regimen (ablative, reduced intensity, non-myeloablative) in which HLA matching is globally associated with a better outcome than HLA mismatching.[35] Finally, among HLA-10/10-matched unrelated donor transplants, the race and ethnicity of the patient influence outcome.[50] Risks of both acute GVHD and relapse are lower in patients of Asian ancestry than other races and demonstrate the importance of non-HLA factors in influencing the clinical outcome.

Single-Locus Mismatched Transplantation

When an HLA-matched donor is not available, transplantation from a donor with one HLA-A, -B, -C, -DRB1, or -DQB1 mismatch may be considered; however, the risks depend on the mismatched locus (Table 106.5). In the largest analysis of HLA in unrelated transplantation to date, the impact of HLA was studied in over 33,000 transplants performed by the international community.[35] The risks of mortality, DFS, non-relapse mortality and acute and chronic GVHD each increased with each additional HLA-A, -B, -C, -DRB1 or -DQB1 mismatched locus. Mortality increased by ≥20% with each additional mismatch. Among single HLA mismatches, HLA-B mismatches were associated with the lowest DFS and highest acute GVHD risk compared to single HLA-DQB1 mismatches, such that a hierarchy of risks can be discerned: HLA-DQB1, HLA-DRB1, HLA-C, HLA-A, HLA-B.

Among HLA-9/10 unrelated donor transplants, the presence of HLA-DRB1 alleles with certain amino acid motifs is associated with higher mortality.[51] In an MHC-wide study of single nucleotide polymorphism (SNP) associations in HLA 9/10 unrelated donor transplants, rs429916 was validated as a marker for mortality. Fine-mapping over 400,000 base pairs of the class II region identified residues 26, 28, and 30 of HLA-DRβ to be the susceptibility feature. Patients whose HLA-DRB1 alleles encode 26F-28E-30Y have a significantly higher risk of mortality than patients whose HLA-DRB1 alleles encode other residues at these three positions. The frequency of 26F-28E-30Y-positive HLA-DRB1 alleles is higher among individuals of African and Hispanic ancestry than those of White European or Asian backgrounds. The 26F-28E-30Y motif, when present, increases mortality after transplantation regardless of the patient's ethnicity. These results demonstrate that the patient's germline HLA features influence transplant outcome and may aid in pre-transplant risk assessment.

Locus-specific features. Intense efforts directed at identifying HLA features that predict better tolerated ("permissive") mismatches than others ("non-permissive") have identified key concepts: (1) allele compared to antigen mismatches; (2) mismatching for specific amino acid residues in the mature HLA molecule; (3) the level of expression of the mismatched patient allele, and (4) variation residing outside of the peptide-binding region (Box 106.3).

Alleles and antigens. The concept that allele mismatches are associated with lower risks than antigen mismatches was borne out of differences that might provoke different T-cell responses: the number of nonsynonymous substitutions (a change in amino acids) and in the location of the mismatch in the α_1 and α_2 domains of the class I molecule, features affect peptide binding (see Table 106.5). Among HLA-C allele mismatches, the high-frequency C*03:03/C*03:04 allele mismatch is associated with risks comparable to HLA-C-matching and attributed to low cell-surface expression levels.[52] These data are consistent with the early graft failure experience and imply that when faced with a choice between donors with allele or antigen mismatches, selection of an allele mismatch may help to lower risks.

Mismatching at specific HLA residues. The hypothesis that donor-recipient mismatching at certain amino acid substitutions in the class I HLA molecule may be associated with higher post-transplant risks compared with mismatching at other residues has been evaluated in several studies and has particular clinical significance in HLA-DP.[53] HLA-DPB1 T-cell epitope groups correlate with alloreactive T-cell cross-reactivity patterns and predict GVHD risk.

Level of HLA expression. HLA class I proteins are expressed at different levels and this differential expression is a key feature of alloimmunity in infections and autoimmune diseases including HIV-AIDs and Crohn's disease.[54] The level of expression of HLA-C and HLA-DP allotypes is an important feature of the permissivity of mismatches at these two loci.[55,56] The concept behind HLA expression in diseases pertains to the robust presentation of foreign antigens when HLA molecules are expressed at high levels on the cell surface. This contributes to improved immune surveillance. In transplantation, high-expression HLA molecules may provoke a strong attack on host tissues leading to autoimmunity or GVHD in transplantation.

HLA-C. HLA-C expression is regulated in part by rs9264942 ("−35" SNP), which maps equidistant from HLA-B and -C[57] and ablates the miR-148a binding site.[58] In addition to rs9264942, variation in an OCT1 binding site in the promoter provides further control of HLA-C expression.[59] Although each marker is associated with differential HLA-C expression, they do not completely explain its regulation. In HLA-C-mismatched transplantation, as the level of expression of the patient's mismatched HLA-C allotype increases, the risks of acute GVHD and non-relapse mortality increase.[55] Compared to low-expression C*03 and 07 mismatches, high-expression C*01 and 14 mismatches are associated with increased risk when the HLA-C mismatch was also mismatched at residue 116 and for natural KIR ligands. Residue 116 and KIR ligand mismatches that were low-expression had similar risks as HLA-C matches. These data demonstrate that both expression and qualitative features define permissivity.

HLA-DP. The 3′ UTR of HLA-DPB1 is resident to rs9277534 which affects the level of expression of HLA-DP. Haplotypes defined

TABLE 106.5 Impact of Human Leukocyte Antigen Mismatching and Donor Killer-Cell Immunoglobulin-Like Receptor on Outcome of Unrelated Donor Transplantation

Mismatched Locus	Graft Failure	GVHD	Relapse	Survival	Notes
HLA-A	↑[1,2]	↑[4–6]		↓[4,6,7]	Allele and antigen mismatches are similarly risky; in some reports, antigen mismatches are riskier than allele mismatches
HLA-B	↑[2]	↑[4–6]		↓ [6,7]	Insufficient data on allele vs. antigen mismatches
HLA-C	↑[2,3]	↑[4–6,8,9]	Yes[7]	↓[6–8]	Antigen mismatches are much riskier than allele mismatches. C*03:03/03:04 mismatch is low-risk. GVL effect present
HLA-DRB1		↑↓[4–6]		↓[6,7]	Insufficient data on allele vs. antigen mismatches. global trend for lower survival
HLA-DQB1		↓[4]			Only when DQB1 is the only mismatched locus (HLA 9/10)
HLA-DPB1		↑[6,10,13]	Yes[7]	↓[6,7]	GVL effect present
HLA-C Expression		↑[9]			High-expression patient mismatch
HLA-DPB1 T-cell epitope		↑[11]		↓[11,14,15]	TCE non-permissive
HLA-DP expression		↑[16]			High-expression patient mismatch
HLA-B leader		↑[6]			Leader-mismatching
HLA-E				↓[6]	E*01:03 lowers disease-free survival
MICA		↑[17–19]			Heterogeneous data
Missing self			↓[20,21]	↑[20,21]	Protective from AML relapse (when PT-Cy is not used)
Missing ligand			↓[22–26]	↑[22–26]	Lower AML relapse
KIR3DS1		↓[27]		↑[27]	Lower GVHD
KIR haplotype-B			↓[28–31]	↑[28–30]	Lower relapse, heterogeneous data
KIR2DS1+HLA-C1			↓[32–34]	↑[32–34]	Lower AML relapse, heterogeneous data
KIR3DL1 inhibition			↓[34,35]	↑[34,35]	Lower AML relapse, heterogeneous data

BOX 106.3 RESEARCH IN PROGRESS: NEW IMMUNOGENETIC FACTORS FOR CONSIDERATION IN TRANSPLANTATION

Human Leukocyte Antigen

When a human leukocyte antigen (HLA)-matched donor is not available, criteria for the selection of mismatched donors is needed. Beyond prioritizing an allele mismatch over an antigen mismatch, research on the immunogenicity of residues of class I and II molecules and their amino acid substitutions remain important concepts. Hypervariable positions having a direct influence on the peptide-binding region of the molecule have been most commonly studied, and show that some amino acid substitutions at certain positions are more detrimental than others; these include residues 99 and 116 of HLA-C, residue 9 of HLA-B, and residues that define hypervariable regions of HLA-DP. Further elucidation of the features of residue mismatching will provide more specific information on the combinations of mismatches that are permissive.

The level of HLA expression of patient mismatches influences GVHD. A minority of the putative variants that control HLA expression are known, and more information is needed to understand the mechanisms. The role of non-coding variation such as the HLA-B leader dimorphism will advance understanding of the mechanisms of T- and natural killer (NK)-cell recognition and provide new avenues for donor selection.

A role for highly conserved HLA haplotypes and transplant outcomes is emerging in selected populations. Haplotype content and organization in ethnically diverse populations will continue to provide invaluable information.

Killer-Cell Immunoglobulin-Like Receptor

Donor NK alloreactivity in hematopoietic cell transplantation (HCT) is manifested as improved control of myeloid malignancy, leading to a reduced risk of leukemia relapse and increased survival following transplantation. It has become increasingly evident that killer-cell immunoglobulin-like receptor (KIR) driven donor NK effects can occur in the HLA-matched setting. Several models of NK activation in transplantation have been tested in retrospective studies in efforts to use KIR and HLA genotypes to select advantageous donors and improve transplant outcomes.

Donors with KIR genotypes encoding activating KIR provide protection from relapse of myeloid malignancy following transplantation, but additional information is needed to understand how HLA moderates this benefit. Donors with KIR3DL1 subtypes that signal less NK inhibition also provide protection from disease relapse. KIR-based donor selection that promotes NK activation while minimizing NK inhibition will therefore provide the greatest benefit to patients with myeloid malignancies. Novel findings in NK education will continue to guide future studies of KIR and HLA in transplantation.

Novel Markers

HLA haplotype encodes additional genes that have clinical relevance. Future research into the identification of the causative genes will shed light on the pathways involved in graft-versus-host and host-versus-graft allorecognition. The use of next-generation sequencing (NGS) methods for both clinical and research applications will accelerate the identification of novel markers, particularly in non-coding regions of HLA genes.

by HLA-DPB1 exon 2 and rs9277534 permit two families of alleles to be defined: low-expression rs9177534A and high-expression rs9277534G. Haplotypes have been confirmed in a large study of registry donors.[60] In HLA-11/12 transplants with one HLA-DPB1 mismatch, mismatching against a high-expression patient allele was associated with significantly higher acute GVHD than mismatching against a low-expression allele.[56] The role of HLA-DP expression in permissive mismatches was recently validated in Japanese transplants[61] and in solid organ transplantation in which high-expression rs9277534G HLA-DP antigens are associated with a stronger B-cell flow crossmatch compared to low-expression rs9277534A antigens.[62] Both T-cell epitope (TCE) and HLA-DP expression inform GVHD.[63]

HLA-DRB3, DRB4, DRB5. The low-expression loci HLA-DRB3, -DRB4, and -DRB5 contribute to clinical outcome.[52] The cumulative impact of multi-loci mismatching inclusive of DRB3/4/5 on mortality is significant, particularly when three or more mismatches are present. These data suggest that when an HLA-DRB1-mismatched donor is identified, additional characterization of HLA-DRB3/4/5 on relevant HLA-DR haplotypes is warranted.

Variation outside of the HLA peptide-binding groove. HLA research has focused on the peptide-binding groove because of the role of antigen presentation in immunity and GVHD. Variation encoded outside of the peptide-binding region may also affect the outcome, particularly when it defines haplotypes across an HLA genetic region. The HLA-B leader is an example of a functional polymorphism that is encoded within the HLA-B locus, but outside of the peptide-binding region.[35]

The HLA-B leader is encoded by exon 1. A C/T dimorphism at rs1050458 (position -21) gives rise to leader peptides with either methionine (M) or threonine (T) at the second residue of the leader peptide. HLA-B alleles that encode M-leaders are a family distinct from alleles that encode T-leaders. M- and T-leaders differentially influence HLA-E expression and the strength of inhibitory and activating NK and T-cell responses.[64]

In HLA-9/10 unrelated donor transplants with one HLA-B mismatch (and one HLA-B match), the leaders of the mismatched patient and donor alleles as well as the leader of the matched allele both influence GVHD risk.[35] When the patient/donor mismatched alleles are both from the same leader family (both M or both T), acute GVHD is significantly lower than when the mismatched alleles are derived from different leader families (an M-leader allele mismatched with a T-leader allele). When the matched allele encodes an M-leader, GVHD is higher than when the matched allele has a T-leader. These data implicate a polymorphism outside of the peptide-binding groove in transplant outcome. Both HLA-B haplotypes contribute to the immune response. Use of the HLA-B leader to select permissive HLA-B mismatches may provide patients with options.

Importance of Killer-Cell Immunoglobulin-Like Receptor in Relapse After Transplantation

KIR ligand incompatibility and missing self in HLA-mismatched HCT. The clinical significance of donor KIR genotype in allogeneic HCT first came to light in the setting of HLA-haploidentical HCT using $CD34^+$-selected allografts, where the high degree of HLA-mismatching led to the frequent circumstance in which a KIR ligand present in the donor was lacking in the recipient, thereby fulfilling the criteria for the "missing self" from the standpoint of the donor NK cell (see Table 106.5). Citing missing self due to KIR ligand incompatibility in the graft-versus-host direction, investigators reported a lower risk of relapse of myeloid malignancy following HCT.[65] The observation that favorable HCT outcomes were associated with the absence of donor KIR ligands in the recipient suggested that donor-derived NK alloreactivity was the source of leukemia control and that KIR receptors were the mediators of the disease control. The successful isolation of educated, KIR^+ donor NK clones reacting according to missing self in vitro provided further accuracy in predicting leukemic control in patients lacking donor KIR ligands.[66] That myeloid malignancies were more sensitive to NK control compared to lymphoid malignancies provided additional clues to the biology of NK cells, which not only require a lack of inhibitory signals from the target cell to unleash cytotoxicity but also require simultaneous activating signals. Indeed, myeloid malignancies express abundant activating ligands, such as MIC-A, a protein recognized by the NKG2D activating receptor on NK cells.[67] Interestingly, a recent study of transplantation using unmanipulated haploidentical T-cell-replete allografts with the administration of post-transplant cyclophosphamide for prevention of graft-versus-host disease did not replicate the original findings of protection from disease relapse, possibly due to the elimination of mature donor KIR^+ anti-leukemic NK cells in the allograft.[68]

Missing ligand effect in HLA-matched HCT. Although HLA-mismatched HCT is becoming more common, the prevailing preference is for a stem cell donor that is matched for as many HLA alleles as possible, with possible exceptions for permissive mismatching at HLA-DP.[56] By definition, matching donor and recipient for HLA alleles results in KIR ligand matching, which eliminates the possibility for educated NK alloreactivity due to missing self. It was therefore surprising that a lack of KIR ligands was found to be predictive of AML relapse following HLA-matched sibling transplantation, where homozygosity for HLA-C1, HLA-C2, or HLA-Bw6 was predictive of lower relapse and higher survival.[69] The lack of KIR ligands (e.g. lack of HLA-C2 ligand in HLA-C1 homozygous patients, lack of HLA-Bw4 in HLA-Bw6 homozygous patients) invoked the possibility that uneducated NK cells expressing the KIR receptors for the "missing ligands" could be activated by the post-HCT inflammatory environment for cytotoxicity.[70] Findings of improved outcomes with lack of KIR ligands have since been replicated with HLA-matched sibling and unrelated donor allografts,[71–73] and HLA-mismatched umbilical cord allografts.[74]

KIR B-haplotypes. Capturing donor NK alloreactivity according to missing self and missing ligand mechanisms of NK activation, however, ultimately depends on the recipient's HLA genotype, which encodes the patient's KIR ligands and cannot be altered. Efforts to identify benefits associated with donor KIR gene content irrespective of KIR ligand has yielded positive findings, again compellingly confined to the AML patient population. KIR3DS1 is an activating variant of the inhibitory KIR3DL1 gene and characterizes KIR B-haplotypes with telomeric activating KIR.[7] A large retrospective study of patients undergoing unrelated donor HCT identified the association of donor KIR3DS1 with lower GVHD and higher overall survival, with increased benefit seen in donors exhibiting more than one KIR3DS1 copy.[75] A separate study revealed that both centromeric B-haplotypes (e.g. those containing KIR2DS2) and telomeric B-haplotypes confer a protective effect from AML relapse with superior survival, but that centromeric B-haplotypes (cenB) were the more protective of the two.[13] Accordingly, homozygosity for cenB was associated with the greatest protection from AML relapse. Together, these data support the selection of a donor with KIR B-haplotype to reduce relapse and GVHD in patients with myeloid malignancies.

KIR2DS1 and HLA-C1. The telomeric KIR2DS1 is the only activating KIR that contributes to NK education, as evidenced in vitro by progressive hyporesponsiveness among KIR2DS1$^+$ NK cells from donors with increasing HLA-C2 allele content.[19,48,49] Correspondingly, the protective effect of donor KIR2DS1 against AML relapse following HLA-compatible HCT is lost in patients whose donors are HLA-C2 homozygous.[76,77] Interestingly, donor HLA-C2 homozygosity silences the benefits seen with all KIR haplotype-B donors and not just those with KIR2DS1.[76,78] Thus, to gain the protective effects of donor KIR2DS1$^+$ and other activating KIR, an HLA-C1 donor is required.

KIR3DL1 and HLA-Bw4 subtypes. NK cells expressing the same KIR receptor and derived from individuals with similar KIR ligands can still display a wide variation of response capacity, due to allele-encoded differences in receptor expression, ligand expression, and affinity between receptor-ligand pairs.[18,79] The KIR-HLA relationship most illustrative of how polymorphism impacts NK function, is the KIR3DL1/HLA-Bw4 combination. KIR3DL1 alleles differ significantly in surface expression, with variants expressed at high or low density on the surface and with one common variant retained intracellularly, leading to the subtype designations of KIR3DL1-h, KIR3DL1-l, and KIR3DL1-n.[80–82] HLA-B Bw4 alleles can be segregated based on dimorphism at amino acid position 80 into subtype groups characterized by an isoleucine (Bw4-80I) or threonine (Bw4-80T) residue. Combinations of high vs low expression KIR3DL1 subtypes with Bw4-80I or Bw4-80T subtypes generate distinct differences in response capacity and inhibitory strengths, partially enhanced by differences in binding affinities.[18,79,83] In individuals with two KIR3DL1 alleles, the low-expression allele dominates, leading to a compound subtype designation of KIR3DL1-L, and in individuals with two HLA-Bw4 alleles, the Bw4-80I allele dominates. High inhibition combinations include KIR3DL1-H + Bw4-80I and KIR3DL1-L + Bw4-80T, while low inhibition combinations include KIR3DL1-H + Bw4-80T and KIR3DL1-L + Bw4-80I.

Among AML patients receiving a 9/10 or 10/10 HLA allele-matched unrelated donor HCT, those whose donor KIR3DL1 subtype is paired with a low inhibitory HLA-B subtype experience lower relapse following HCT, compared to patients whose donor KIR3DL1 subtype is paired with a high inhibitory HLA-B subtype.[83] Patients whose donors express a non-inhibitable KIR3DL1 allele (e.g., KIR3DL1-n or KIR3DS1) or who lack the HLA-Bw4 epitope (e.g., HLA-Bw6 homozygous) experienced relapse rates similar to patients with low inhibitory donor KIR3DL1/HLA-Bw4 relationships. Because KIR3DL1 is essentially ubiquitous within the population, and its expression subtypes are fairly equally distributed, identifying an unrelated donor with a low/no KIR3DL1 inhibition subtype for an HLA-Bw4$^+$ patient is an achievable goal.

Mixed results for KIR and HCT outcomes. The prospect that donors can be selected based on KIR and HLA genotypes to harness NK alloreactivity is bolstered by compelling results from numerous retrospective trials, frequently involving cohorts of more than 1000 patients. Validation of the beneficial impacts of each of these KIR-HLA models has, however, provided mixed results. A retrospective study of donor KIR B-haplotypes in recent transplants found lower AML relapse and higher survival following HCT but only in patients who received reduced-intensity, and not myeloablative, conditioning;[78] another study, however, found no benefit of KIR B-haplotypes in reduced intensity HCT.[84] While one retrospective analysis found no apparent benefit from donor KIR B-haplotypes in pediatric HCT patients with either myeloid or lymphoid malignancies,[85] another showed a benefit of donor cenB (but not telomeric-B haplotypes) in pediatric ALL patients.[86] Similarly, a large retrospective study was not able to validate the protective effects of the donor KIR2DS1 + HLA-C1 combination and low inhibition donor KIR3DL1 + HLA-Bw4 combinations.[87] A greater understanding of NK alloreactivity, its predictive genetics, and the transplant conditions that favor its effects is still required. Well-designed prospective clinical trials of donor selection based on biologically supported KIR and HLA models will undoubtedly help to resolve some of these discrepancies.

SUMMARY

Based on a large-scale registry and consortium studies, recommendations for donor selection are as follows: (1) If the patient has many potential HLA-8/8 donors, additional matching for HLA-DQB1 (HLA-10/10) and HLA-DPB1 (HLA-12/12) may further enhance patient outcomes. (2) When an HLA-10/10 matched donor cannot be identified, the use of a donor mismatched for a single HLA-DQB1 allele can be considered. (3) When HLA-10/10 donors are available, selection of a 12/12 donor matched at HLA-DPB1 may further lower GVHD risks. (4) When an HLA-12/12 donor is not available, consideration of HLA-11/12 donors with a single HLA-DPB1 mismatch using either the TCE or expression algorithm, will help to lower GVHD risk. (5) Multiple mismatches are less well tolerated and should be limited. (6) When HLA-DRB1-mismatched donors (7/8 or 9/10) are identified, assessment of HLA-DRB3, DRB4 or DRB5 may help to uncover coincident mismatching at these loci; cumulative mismatching at multiple HLA-DRB genes increases risks after transplantation and should be avoided. (7) Polymorphisms outside of the classical HLA loci may be clinically significant. (8) If an HLA-mismatched donor cannot be avoided, selection of a donor whose KIR ligands are missing in the patient may protect the patient from relapse of myeloid malignancy. This protection may be lost, however, with the use of post-transplant cyclophosphamide. (9) In HLA-matched HCT, the selection of an HLA-C1$^+$ KIR2DS1$^+$ donor may reduce the risk for myeloid malignancy relapse. (10) Selection of a donor with a KIR B-haplotype (e.g., centromeric KIR2DS2 or telomeric KIR3DS1) may provide protection against relapse of myeloid malignancy. (11) For patients who are HLA-Bw4$^+$ and for whom multiple donors are available, consideration should be made to select a donor with a KIR3DL1 subtype predicted to have low inhibitory interaction with the patient's HLA-Bw4 subtype to decrease the risk of post-HCT myeloid leukemia relapse and increase survival (see Table 106.5).

Beyond Classical Human Leukocyte Antigen

The MHC is the most diverse region in the human genome known to date, encoding more than 300 loci involved in immune function within the extended 7.6-megabase (Mb) region.[88] Hence, current donor matching is performed for less than 5% of the total gene content of the MHC. In addition to the classical HLA loci, the MHC is residence to the nonclassical HLA-E, HLA-F, HLA-G, MICA, and MICB genes. The recent analysis of HLA-9/10 transplants identified donor HLA-E*01:03 to be associated with lower DFS.[35] The association of HLA-E*01:03 with outcome provides new insight into dual pathways: potential T-cell as well as CD94/NKG2 NK recognition of the ligand.

Information on MICA in transplantation has become available.[89–91] In some series, HLA-10/10 transplants had higher severe acute GVHD when the patient and donor were MICA-mismatched or when the mismatch involved residue 129.[91] However, in other series, no association of MICA alleles or mismatching can be demonstrated.[89,92] The clinical significance of MICA alleles and mismatching remains an important research question.

The Major Histocompatibility Complex in the Next-Generation Sequencing Era

The availability of NGS methods has uncovered unprecedented levels of haplotype-associated variation of the MHC. The routine use of NGS-based HLA typing is redefining the landscape of the MHC. Emerging data indicate that HLA-10/10 unrelated donor pairs harbor substantial degrees of undetected variation; furthermore, the clinical outcome is superior when patients and donors are matched across class I genes by NGS criteria.[93] As more NGS information becomes available, it is anticipated that both coding and non-coding variation with biological significance will be discovered. In this way, the validation and cataloguing of human genetic variation remain a vital resource for future research (see Box 106.3).

CHAPTER 107

HAPLOIDENTICAL HEMATOPOIETIC STEM CELL TRANSPLANTATION

Stefan O. Ciurea

INTRODUCTION

Allogeneic hematopoietic stem cell transplantation (alloHSCT) is an effective treatment for a wide range of hematologic malignancies, nonmalignant hematologic diseases, and immunologic disorders.[1] Sources of donor stem cells for alloHSCT include human leukocyte antigen (HLA)-matched siblings (MSD), HLA-matched unrelated adult donors (MUD) matched at least at HLA-A, -B, -C, -DRB1, HLA-mismatched unrelated donors, unrelated umbilical cord blood, and HLA half-matched related donors, mismatched at 2 or more HLA antigens (haploidentical donors, HRD). Haploidentical donors are matched at one full haplotype (see later) with various degree of matching in the other haplotype (6 to 10 out of 12 allele match). Historically, the most important consideration in choosing between graft sources has been the degree of match between donor and recipient. A fully HLA-matched sibling has been traditionally the preferred donor because transplants using such donors have been associated with the lowest incidence of treatment-related complications and best overall survival (OS). Unfortunately, only 25% to 30% of patients referred for transplantation have an MSD available. For other patients, a MUD has been the preferred alternative; however, availability of a MUD varies widely based on patient race/ethnicity, from approximately 70% for individuals of Northern European descent to less than 20% for African Americans or Asians.[2] In addition, a longer time to obtain the unrelated donor cells, on average of 3 to 4 months, may expose the patients in urgent need for a transplant to risk of disease progression.[3] Increased HLA mismatching has been associated with increased alloreactivity between donor and recipient T cells, leading, in general, to worse outcomes including higher risks of graft rejection, graft-versus-host disease (GVHD), and nonrelapse mortality (NRM). Over the past two decades, significant progress has been made in mitigating alloreactive reactions between the donor and recipient, which has enabled an increase in use of haploidentical donors for transplantation, now the fastest growing source of hematopoietic stem cells,[4] with improved transplant outcomes, similar to HLA-matched donor transplants, and potential to become the alternative donor of choice for patients without a MSD, at least for those in need of an urgent transplant.

There are several advantages of using haploidentical donors for transplantation (see box on The Increasing Popularity of Human Leukocyte Antigen–Haploidentical Donors):

1. *Near-universal availability of highly motivated donors:* Patients have an average of 2.7 potential HLA-haploidentical donors among first-degree relatives;
2. *Rapid availability:* As compared with MUDs, a haploidentical donor can be identified, screened, and collected within 2 weeks, and transplant can be performed in 3 weeks;
3. *Low cost of graft acquisition:* The costs of graft acquisition from MUD and especially from umbilical cord blood banks can be substantially higher than from related donors, including haploidentical donors[5];
4. *Adequate doses of HSCs:* An adequate number of HSCs can be obtained from HLA-haploidentical donors for adult recipients, as compared with umbilical cord blood grafts. The number of total nucleated calls infused has been correlated with all transplant outcomes[6,7];
5. *Availability of the donor for repeated donations of HSCs (stem cell boost) in case of poor graft function or therapeutic cells (lymphocytes) to prevent/treat relapse or viral infections;*

GLOBAL EXPANSION OF HUMAN LEUKOCYTE ANTIGEN–HAPLOIDENTICAL DONORS

The number of human leukocyte antigen (HLA)-haploidentical stem cell transplant procedures performed is increasing on a global scale. China is the leader in HLA-haploidentical ("haplo") stem cell transplants (SCTs) on a per-country basis, perhaps because of the former one-child policy that has nullified the availability of an HLA-matched sibling for many patients. In the past 5 years, the number of haplo transplants performed in Europe and the United States has more than doubled. Reports of successful haplo SCTs are appearing in the published literature from countries with more limited economic resources, such as Brazil, India, and Romania.

There are clinical, practical, and economic reasons for the increasing popularity of HLA-haploidentical SCT. Clinically, results of the procedure have improved dramatically over the past 10 to 15 years, to the point that the outcomes of haplo SCT approach or equal those of HLA-matched sibling or unrelated donor transplantation (see Comparative Outcomes Between Haploidentical and Other Graft Sources). Another major practical advantage of the haplo option is donor availability. A haplo donor can be found for nearly every patient referred for allogeneic SCT, because every biologic child or parent of a patient is HLA haploidentical, and each sibling or half-sibling has a 50% chance of being HLA haploidentical. The likelihood of finding a haplo donor increases further if one is willing to consider second-degree relatives, such as aunts, uncles, nieces, nephews, or cousins, as donors. The wide availability of haplo donors is especially important for members of ethnic minority groups that are underrepresented in registries of volunteer unrelated donors. Relatives, especially parents and children, tend to be highly motivated to donate and can do so more than once if needed to treat graft failure or relapse. The treating center has greater control over the timing of transplants when haplo donors rather than unrelated donors are used. Clinical trials and advances in adoptive cellular therapy of cancer may be easier using related donors because unrelated donor lymphocytes for infusion are regulated by the US Food and Drug Administration as a biologic. Thus an investigational new drug application must be filed for any clinical trial employing the infusion of lymphocytes from unrelated donors, but not for minimally manipulated lymphocytes from related donors.

Finally, the cost of obtaining the graft from haploidentical donors is cheaper compared with stem cells from unrelated adult volunteers or from umbilical cord blood. This, combined with the growing availability of inexpensive methods of graft-versus-host disease prophylaxis for haplo SCT (especially posttransplant cyclophosphamide), makes haploidentical transplants increasingly attractive in countries with limited economic resources and a fixed budget for allogeneic stem cell transplantation. Thus, haploidentical donor transplant as related donor transplants, largely eliminate cost differences compared with HLA-matched related donor transplants.

6. *Potential for a stronger graft-versus-leukemia (GVL) effect:* Increase alloreactive reactions generated by higher degree of HLA mismatch may be associated with a stronger GVL effect compared with MSD transplants, with some studies suggesting a lower cumulative incidence of relapse[8] and an improved survival[9–11]; however, the full potential of this stronger GVL has not yet been fully realized.

HISTORICAL PERSPECTIVE

The major challenge in performing haploidentical HSCT (haploSCT) with conventional GVHD prophylaxis has been overcoming the intense bidirectional alloreactive reactions in the host-versus-graft (HVG) and graft-versus-host (GVH) direction, primarily mediated by donor T cells against recipient's HLA antigens,[12] resulting in high incidence of graft rejection, hyperacute GVHD, and treatment-related mortality.[13] In an analysis of more than 2000 allogeneic transplants performed between 1985 and 1991 and reported to the International Bone Marrow Transplant Registry,[14] compared with MSD transplants and using conventional GVHD prophylaxis, two HLA antigen-mismatched related donor transplants resulted in higher incidence of NRM (55% vs. 21% at 3 years post-transplant), graft failure (16% vs. 1%), moderate-severe acute GVHD (56% vs. 29%), and chronic GVHD (60% vs. 42%). Complete T-cell depletion (TCD) using CD34+ selected grafts has been subsequently used to reduce the incidence of acute GVHD; however, an increased risk of graft rejection and treatment-related mortality secondary to infectious complications emerged.[15–17] Infusion of "mega-dose" CD34+ cells[18] decreased the incidence of graft failure; however, it could not compensate for the almost complete lack of donor T cells (especially memory T cells) in the graft, and a higher incidence of infectious complications, especially viral infections, persisted, which was the main cause of death in these patients.[19] Consequently, it became apparent that complete T-cell depletion cannot provide better outcomes, and various attempts to maintain different lymphocyte subsets in the graft have been subsequently studied.[20,21] The Tübingen and Memphis groups introduced $CD3^+/CD19^+$ depletion rather than positive selection of $CD34^+$ cells to produce a graft that retains other cell subsets in the graft (such as NK cells, monocytes, dendritic cells, and other myeloid cells) that might facilitate a faster immune recovery without excessive GVHD, [22] and generate a lower treatment-related mortality.[20] In one study in adults, all but 1 of 29 patients engrafted; however, grades II–IV acute GVHD occurred in 48% of patients, 8 patients (28%) had NRM, 7 died as a result of infection. The 2-year survival was only approximately 20%. However, this approach appeared to be associated with better outcomes in children. In a study of 46 children receiving $CD3^+/CD19^+$-depleted grafts after myeloablative conditioning, successful engraftment was shown in 88% of patients, and grades II–IV acute GVHD occurred in 20%, grades III–IV acute GVHD in 7%, chronic GVHD in 21%, and NRM in 20%.[22] In this latter study, relapse occurred in 63% of patients after 2 years of follow-up; however, 43% of patients undergoing transplant had active disease at the time of treatment. The increased risk of infection seen after TCD haploSCT may be due to the depletion from the adult donor graft of pathogen-specific memory T cells that provide protection from infections until new donor T cells differentiate from hematopoietic precursors in the recipient thymus. Subsequent research has been focused on infusing grafts containing selected populations of T cells to enhance immune reconstitution without substantially increasing the risk of GVHD. Adding back a fixed number of T cells that have been depleted of alloreactive cells or that have been anergized was proposed, with various degrees of success in improving immune reconstitution post-transplant.[23,24] Several major advances emerged after year 2000, when graft manipulation focused on partial T-cell depletion of alloreactive T cells[25,26] and pharmacologic modulation applied early post-transplant,[27] have made major progress in reducing the incidence of infectious complications post-transplant, without increasing the incidence of GVHD and NRM. These maneuvers have significantly improved survival of patients receiving haploidentical transplantation,[19,28–30] making this graft source an equal alternative to unrelated donor grafts, with similar outcomes and pattern of immunologic reconstitution post-transplant (see Modern Approaches to Haploidentical Transplantatiom).[31–33]

IMMUNOLOGICAL CONSIDERATIONS OF MAJOR HUMAN LEUKOCYTE ANTIGEN MISMATCHED GRAFTS

A haplotype is a set of genes closely grouped together on a chromosome, inherited as a biologic unit. The HLA locus on chromosome 6p13.2 comprises a set of tightly linked genes encoding molecules that present peptide antigens to T cells. The HLA locus contains three regions: (1) Class I region—encodes the "classical" class I HLA genes HLA-A, HLA-B, and HLA-C, which present antigens to $CD8^+$ T cells, as well as nonclassical HLA-E, HLA-F, and HLA-G molecules; (2) Class II region—encodes HLA-DRB1, HLA-DQB1, and HLA-DPB1, which present antigens to $CD4^+$ T cells, as well as nonclassical class II molecules HLA-DM and HLA-DO; (3) Class III region—encodes molecules not known to be involved in histocompatibility reactions. An HLA haplotype is defined as the set of histocompatibility genes present on chromosome 6 which are transmitted together. Each individual has two HLA haplotypes, one inherited from each parent. An HLA-haploidentical donor is a related donor who shares one full haplotype with the transplant recipient, while the degree of HLA matching on the mismatched haplotype may vary between 0 (full haplotype mismatch, 5/10 HLA matched) to 3 (8/10) (of note a 9/10 HLA related donor is not considered a haploidentical donor). Recently, high-resolution HLA typing is usually performed for three HLA class I genes, HLA-A, HLA-B, and HLA-C, and three class II genes, HLA-DRB1, HLA-DQB1, and HLA-DPB1, to confirm that the donor and recipient share at least at one full haplotype as, rarely, mismatches can occur during meiosis (crossover). By definition, a parent and a child are HLA haploidentical to each other, and each biological sibling or half-sibling of a patient has a 50% chance of being HLA haploidentical to each other. Other potential haploidentical donors include second- or third-degree related donors—aunts, uncles, nieces, and nephews, who each have a 50% chance of being HLA haploidentical, and cousins, who have a 25% chance of being HLA haploidentical with the recipient.

Mismatching of HLA alleles or antigens can occur in the GVH direction only, the HVG direction only, or bidirectionally. When the donor is homozygous for an HLA allele but the recipient is heterozygous at the same genetic locus, there is a mismatch in the GVH direction only. Conversely, when the recipient is homozygous for an HLA allele but the donor is heterozygous, there is a mismatch in the HVG direction only. In general, HLA mismatches in the GVH direction favor GVHD, whereas HLA mismatches in the HVG direction predispose to rejection of the hematopoietic stem cell graft mostly by recipient's T cells. The number of HLA mismatches between a haploidentical donor and recipient should be expressed as the number of mismatches in the GVH direction, as well as the number of mismatches in the HVG direction. For example, the patient in Fig. 107.1 differs from sibling 2 by four antigens (and alleles) in the GVH direction and by five antigens (and alleles) in the HVG direction, and from sibling 3 by three antigens (vs. four alleles) in the GVH direction and by three antigens (versus five alleles) in the HVG direction. More recently, molecular mismatches evaluating distinct amino acid configurations on the surface of the HLA molecule that could elicit immune responses (eplets) in both HVG and GVH directions are being evaluated, as early data suggest that could impact transplant outcomes.[34,35]

The biologic mechanisms underlying the high incidence of graft rejection and severe GVHD when crossing major HLA barriers remain to be elucidated; however, two fundamental characteristics of T-cell alloreactivity are likely responsible. The first is the high frequency of

	A1	A2	B1	B2	Cw1	Cw2	DRB1-1	DRB1-2	DQB1-1	DQB1-2

Figure 107.1 HIGH-RESOLUTION HUMAN LEUKOCYTE ANTIGEN TYPING IN A REPRESENTATIVE FAMILY. (A) Nomenclature employed for high-resolution typing. The human leukocyte antigen (HLA) genetic locus is identified by the capital letter after the hyphen. The first two digits after the asterisk are the antigen designation, which facilitates comparisons of results of low- or intermediate-resolution versus high-resolution HLA typing. The four-digit code designates allele level type by high-resolution methods, such as sequence-based typing or a combination of sequence-specific priming and sequence-specific oligonucleotide probes. (B) Family typing. Results of high-resolution HLA typing are shown for the parents. Based upon HLA typing of the children, membership of individual HLA alleles in haplotypes, designated "a," "b," "c," and "d," are assigned. The allele composition of the haplotypes is then used to assign haplotype inheritance in the children. The patient is genotypically HLA matched to sibling 1 and is completely mismatched for both HLA haplotypes with sibling 4. Siblings 2 and 3 are partially HLA mismatched, or HLA haploidentical, to the patient, and would be considered potential donors for allogeneic stem cell transplant only if sibling 1 is not a suitable or willing donor. (C) High-resolution HLA typing of the patient is aligned with typing of the HLA-haploidentical siblings to facilitate analysis of the degree of mismatching in both the rejection (host-versus-graft) and graft-versus-host directions. Alleles of the shared haplotype are aligned in columns A1, B1, Cw1, DRB1-1, and DQB1-1. Alleles that are mismatched in the graft-versus-host direction are in *blue boxes*, whereas alleles that are mismatched in the host-versus-graft direction are outlined in *red boxes*.

T cells reactive against allogeneic HLA molecules. T cells recognize a complex determinant comprising specific amino acid residues of the HLA molecule as well as amino acid residues of the bound peptide. It has been estimated that there are 50,000 to 100,000 copies of each HLA molecule on a cell surface, with as many as 5000 different peptides being presented. Each allogeneic HLA molecule provides as many as 5000 distinct recognition units corresponding to 5000 distinct alloreactive T cells. In contrast, a non-HLA or "minor" histocompatibility antigen consists of a single allelic peptide presented by a single species of HLA molecule. The frequency of T cells reactive to a single minor histocompatibility antigen is on the order of 1 in 50,000 the frequency of anti-HLA alloreactive T cells.[12] The higher frequency of T cells reactive to allogeneic HLA molecules compared to minor histocompatibility antigens corresponds to a higher incidence of graft rejection and GVHD after HLA-haploidentical SCT than after HLA-matched SCT. The second property of alloreactive T cells that contributes to a high incidence of graft failure and GVHD after haploSCT is a significant proportion of HLA-alloreactive memory T cells,[36] even in donors and recipients who have not been exposed to allogeneic HLA molecules through pregnancy or blood transfusions. T cells that are immunized against environmental antigens, especially viruses, can cross-react against allogeneic major histocompatibility complex (MHC) molecules.[37,38] The phenomenon, in which viral infection triggers cross-reactive memory against allogeneic HLA molecules, is termed *heterologous immunity* and may be a powerful barrier to the establishment of donor hematopoietic cell chimerism[39] or the induction of tolerance to transplanted organs.[40] Unlike naïve T cells, which are sensitive to chemotherapy-induced apoptosis and to immunologic tolerance induction by antigen without costimulation,[41] memory T cells are more resistant to chemotherapy-induced death, can induce costimulatory signals on antigen-presenting cells that they encounter,[42] and are resistant to tolerance induction by regulatory T cells (Tregs)[43,44] or to T-cell–depleting antibodies.[45–47] The presence and substantial number of memory T cells reactive to allogeneic HLA molecules make control of graft rejection and GVHD more challenging after haploidentical versus HLA-matched transplantation.

B cells and NK cells also participate in the immune response to HLA-mismatched tissues. Allogeneic HLA molecules can elicit the formation of alloantibodies. Preexisting donor-specific antibodies

(DSA) against HLA molecules are a major risk factor for development of primary graft failure after HLA-haploidentical SCT.[48,49] Pregnancy and blood transfusions are sensitizing events that can lead to the formation of antibodies against HLA molecules. Pregnancy is the main mechanism of allosensitization, evident by the fact that the highest DSA levels were found in parous women.[50] The prevalence of DSA in parous women has been reported to be as high as 42%[51]; such sensitization is directed against unshared HLA molecules expressed by their children (father's HLA antigens).

DSA can be detected by flow cytometry using a Luminex platform using beads coated with single HLA molecules or by complement-dependent cytotoxicity (CDC) testing, in which the patient's serum is mixed with donor lymphocytes in the presence of complement.[50] In one study, a positive crossmatch for anti-donor lymphocytotoxic antibodies was associated with a 2.3-fold increased risk of graft failure.[52] Donors with high DSA levels, especially with complement-binding DSAs and/or a positive CDC crossmatch, are, in general, avoided for transplantation, unless a significant response to desensitization treatment is accomplished, as discussed later in this chapter.

Natural Killer Cell Alloreactivity After Allogeneic Transplantation

NK cells are a group of lymphoid cells part of the innate immune system capable of recognizing and eliminating malignantly transformed or virally infected cells. NK cells may play a significant role in inducing GVL effects after haploSCT in humans. Unlike T and B cells, they do not express rearranging receptors for antigen, but like $CD8^+$ T cells, they express receptors for HLA class I molecules, including HLA-B and HLA-C, secrete interferon-γ, and kill target cells via granzyme- and perforin-mediated cytotoxicity. Karre and Kiessling initially proposed in the "missing self" hypothesis as mechanism of action for NK cells.[53,54] It was subsequently found that NK cells are able to detect and rapidly eliminate virally infected or tumor cells that have downregulated cell surface expression of MHC class I molecules to evade the $CD8^+$ T-cell immune response. The molecular basis of NK-cell alloreactivity is incompletely understood; however, it involves a dynamic balance of signals through activating as well as inhibitory receptors on the surface of the NK cells. The killer immunoglobulin-like receptors (KIRs) are encoded by a set of linked genes called the leukocyte receptor complex (LRC) on human chromosome 19q13.4.[55] KIRs contain two or three extracellular Ig-like domains and either a short (S) or a long (L) cytoplasmic tail, which mediate activating or inhibitory signals, respectively. The LRC is marked by significant interindividual variation in KIR gene content as well as significant allelic variation in individual KIR genes.[56] As a consequence, the KIR locus is second only to the HLA locus in the number of polymorphisms, and unrelated individuals are unlikely to share KIR genotypes.

Distinct HLA class I molecules comprise the ligands for specific inhibitory KIRs (iKIRs). An organizing principle of NK-cell biology is that NK-cell self-tolerance is mediated by inhibitory signals delivered by self HLA class I molecules through iKIRs. The ontogeny of receptor expression on individual NK cells is poorly understood, but it is currently thought that each NK cell expresses at least one inhibitory receptor for a self HLA class I molecule.[57] There are four distinct categories of HLA ligands for iKIRs (Fig. 107.2). The C1 group of HLA ligands is characterized by the presence of an asparagine residue at position 80 of the HLA-C molecule and is recognized by either KIR2DL2 or KIR2DL3. The complementary C2 group of HLA ligands is distinguished by a lysine residue at position 80 of the HLA-C molecule and is recognized by KIR2DL1. The Bw4 serologic group is recognized by KIR3DL1. Finally, KIR3DL2 recognizes HLA-3 and HLA-11 molecules. Developing NK cells undergo a host MHC class I–dependent functional maturation process, termed *licensing*[58,59] or, more recently, *education*.[60] Education endows an NK cell with the ability to kill MHC class I–deficient targets but also provides a mechanism for self-tolerance because the same MHC class I ligand that licenses the developing NK cell also inhibits the activity of the mature NK cell. Licensing is not an all-or-none phenomenon, and there are degrees of licensing depending upon the affinity of an iKIR for its HLA ligand. Furthermore, there is evidence that transplanted NK cells can attune themselves to the new HLA environment, indicating that NK-cell alloreactivity is a complex and dynamic phenomenon.[61] Because the genes comprising the LRC and the HLA locus are on chromosomes 19 and 6, respectively, KIR and HLA molecules are inherited independently, so individuals can inherit an iKIR but not its ligand, resulting in an NK cell that cannot be licensed during development. Unlicensed NK cells would be predicted to be poorly functional; unexpectedly, however, they dominate the early response to cytomegalovirus (CMV) infection in mice,[62] and they also may be potent mediators of antibody-dependent cellular cytotoxicity.[63] DNA damage resulting from transplant conditioning or inflammatory conditions such as viral infection may be sufficient to induce stress ligands of NK-cell activation receptors,[64] break tolerance in unlicensed NK cells, and generate autoreactivity,[65–67] including tumor regression. In contrast to HLA-matched transplants, where donors and recipients express the same ligands for iKIRs, in HLA-haploidentical SCTs, the recipient may lack the HLA ligand for the iKIR on a licensed donor NK cell, releasing the cell from inhibition, and resulting in donor NK-cell alloreactivity. Unlicensed donor NK cells may also be activated by a dominance of stimulatory NK-cell ligands in the inflammatory milieu of a conditioned recipient, but this scenario is not unique to HLA-haploidentical SCT and may also occur after HLA-matched SCT as long as the recipient lacks HLA ligands for iKIR molecules. Although the mechanisms of NK-cell alloreactivity remain to be fully elucidated, there is great interest in harnessing their activity for preventing or controlling relapse of hematologic malignancy after HLA-haploidentical SCT.[68]

Models of Natural Killer Cell Alloreactivity After Transplant

The KIR ligand incompatibility model was first formulated by Ruggeri et al.[69–71] to account for NK alloreactivity after rigorously T-cell–depleted, stem-cell–enriched, HLA-haploidentical SCT.[18,72] The model predicts NK cell alloreactivity when the donor expresses, but the recipient lacks, an HLA ligand (HLA group C1, C2, or Bw4) for an iKIR. In this situation, the donor is predicted to contain NK cells that are activated by recipient cells lacking expression of that HLA molecule. Support for the ligand incompatibility model was provided by the ability to generate donor alloreactive NK clones in all 51 ligand incompatible donor—recipient pairs but in none of the 61 donors who were KIR ligand matched with their recipients.[71] NK alloreactivity in the GVH direction was predicted to have three functional consequences[70]: (1) a GVL effect arising from donor NK cytotoxicity against leukemia cells; (2) a decreased rate of graft rejection arising from donor NK-cell killing of host T cells; and (3) a decreased rate of GVHD arising from donor NK-cell elimination of host antigen-presenting cells such as dendritic cells, which are required to initiate GVH reactions.[73] This group (hereinafter the Perugia group) has demonstrated a strong antitumor effect of KIR ligand incompatibility in acute myeloid leukemia (AML) but not in acute lymphoblastic leukemia (ALL) patients undergoing T-cell depleted haploidentical transplantation.

The missing ligand model predicts NK-mediated GVH reactions when the transplant recipient is missing at least one of the three major classes of HLA ligands for iKIR. The missing ligand model differs from the ligand incompatibility model only in that it does not require the presence on donor cells of the HLA ligand that is missing in the recipient. Consequently, donors who are predicted by the ligand incompatibility model to contain alloreactive NK cells against their recipients are a subset of the donors who are predicted by the missing ligand model to contain anti-recipient alloreactive NK cells. The KIR

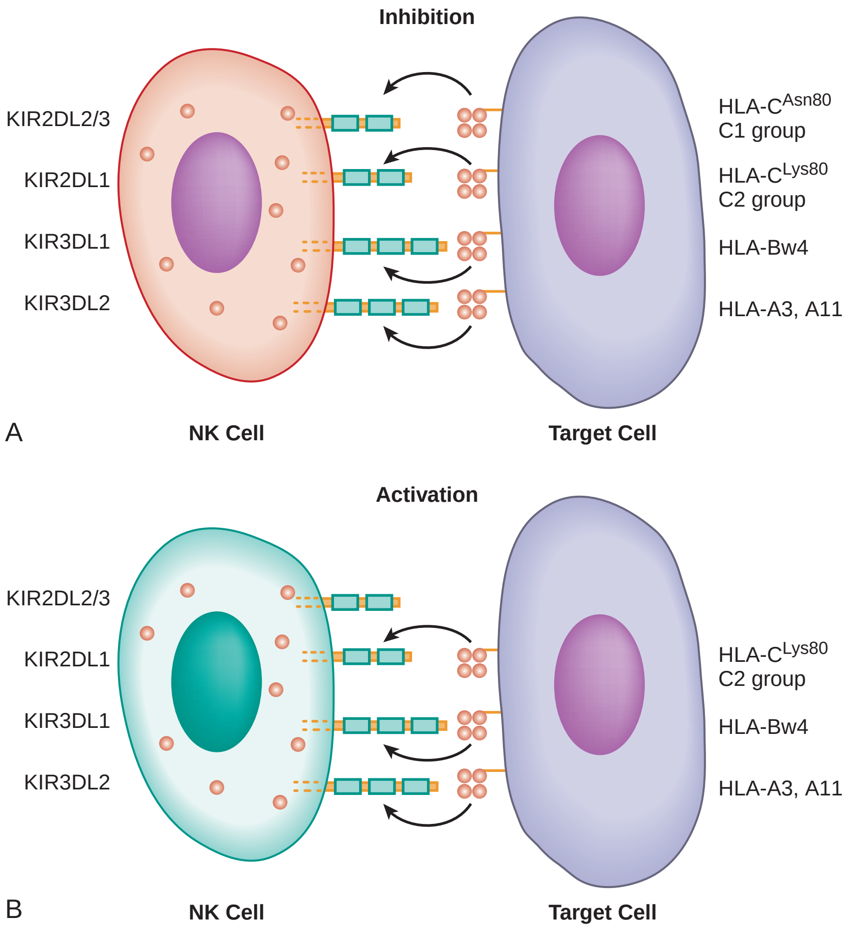

Figure 107.2 INTERACTIONS BETWEEN INHIBITORY KILLER IMMUNOGLOBULIN-LIKE RECEPTORS AND THEIR HUMAN LEUKOCYTE ANTIGEN LIGANDS OF RELEVANCE TO NATURAL KILLER CELL ALLOREACTIVITY AFTER ALLOGENEIC STEM CELL TRANSPLANT. For convenience, a single natural killer (NK) cell expressing four distinct inhibitory killer immunoglobulin-like receptors (iKIRs) is shown. Each NK cell need express only one molecular species of iKIR for functional maturation to occur. Individual members of the human leukocyte antigen (HLA)-C1, HLA-C2, and HLA-Bw4 groups are listed in Table 107.1. (A) High-resolution HLA typing is required to determine whether specific alleles of HLA-B and HLA-Cw are ligands of specific iKIRs. HLA typing of the recipient and KIR genotyping of donor NK cells are incorporated into the ligand incompatibility, receptor ligand, and missing ligand models of NK cell alloreactivity. Interactions between KIR3DL2 and HLA-A3 or HLA-A11 are generally not considered in these models. (B) Schematic view of missing ligand model. When the recipient cell lacks one or more HLA ligands (C1 is missing) for the licensed donor inhibitory KIR, the NK cell alloreactivity occurs in the graft-versus-host direction, possibly leading to the graft-versus-tumor effect.

ligand incompatibility and missing KIR ligand models were compared for their ability to predict relapse after T-cell–replete (TCR), unrelated SCT for hematologic malignancies.[74] Among recipients of HLA-mismatched transplants, recipient homozygosity for HLA-B or HLA-C KIR epitopes was used to define “missing” KIR ligands and was associated with a decreased hazard of relapse (hazard ratio [HR], 0.61; 95% confidence interval [CI], 0.43 to 0.85; $P = .004$). The effect was observed in patients with AML, chronic myeloid leukemia, or ALL. The same effect was not observed in HLA-identical transplants. KIR ligand incompatibility was not associated with a decreased risk of relapse in recipients of either HLA-mismatched or HLA-matched grafts.

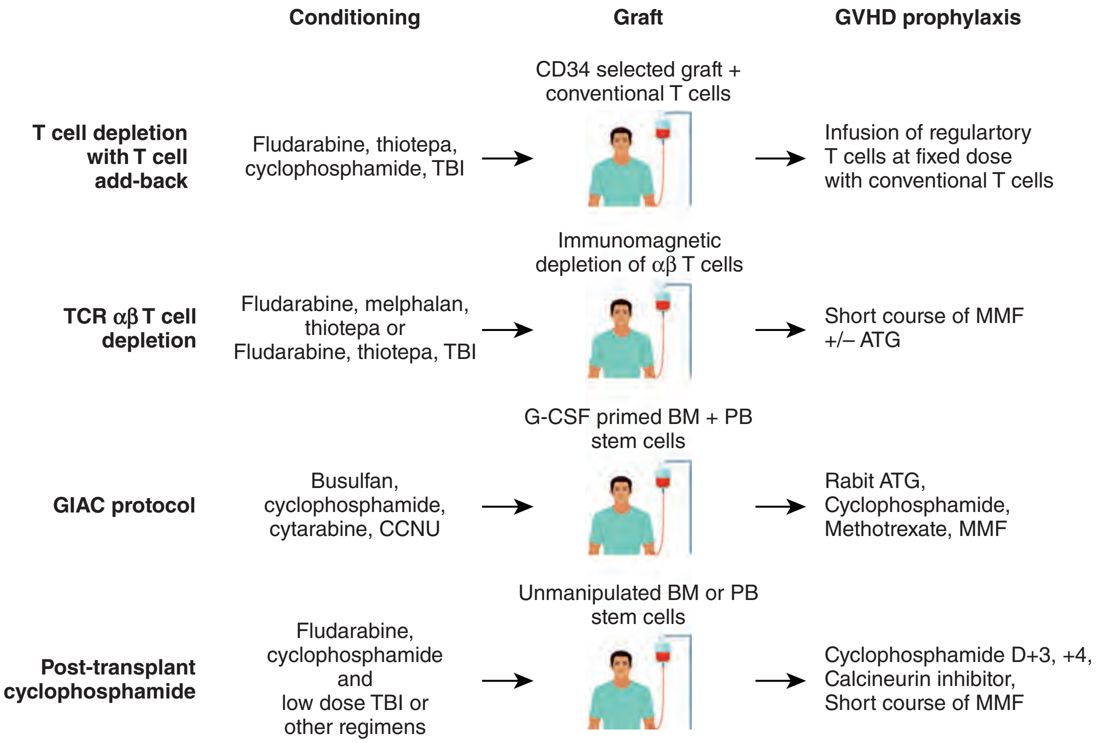
With novel approaches to haploidentical transplantation, especially using post-transplantation cyclophosphamide, there has been a renewed interest in harnessing antitumor effect of NK cells. Although several large retrospective studies failed to show a survival benefit of a KIR ligand mismatched donor as described by the Perugia group[35,75] and cannot be recommended now for donor selection, at least for T-cell replete haploidentical transplants (see Selection of Donors for Haploidentical Transplantation),[76] recent data outlined the role of NK cells infused with the graft in prevention of GVHD, relapse, and survival post-transplant.[7]

MODERN APPROACHES TO HAPLOIDENTICAL TRANSPLANTATION (FIG. 107.3)

Refinements to the T-Cell Depletion Platform to Improve Immune Reconstitution

Early studies of TCD HLA-haploidentical SCT were characterized by lower incidence of GVHD; however, patients experienced a higher incidence of engraftment failure and high NRM, mostly due to infectious complications related to a significant delay in immunologic reconstitution.[19,33,77] These outcomes spurred efforts to improve engraftment rate and immune reconstitution after TCD haploSCT.

In order to improve immunologic reconstitution after transplant, the Perugia group proposed administration of a fixed dose of conventional T (Tcons) cells after TCD haploidentical transplantation, and, to prevent development of severe GVHD, infusion of immunomagnetically selected Tregs 4 days before transplant followed by Tcons cells on the same day as the TCD allograft.[78,79] In the first study of 28 patients only two developed grades II–IV acute GVHD, and both received the highest T-cell doses in the study cohort, while no chronic GVHD was observed.[78] T-cell reconstitution was improved with



Conditioning
Graft
GVHD prophylaxis
T cell depletion with T cell add-back
Fludarabine, thiotepa, cyclophosphamide, TBI
CD34 selected graft + conventional T cells
Infusion of regulartory T cells at fixed dose with conventional T cells
TCR αβ T cell depletion
Fludarabine, melphalan, thiotepa or Fludarabine, thiotepa, TBI
Immunomagnetic depletion of αβ T cells
Short course of MMF +/– ATG
GIAC protocol
Busulfan, cyclophosphamide, cytarabine, CCNU
G-CSF primed BM + PB stem cells
Rabit ATG, Cyclophosphamide, Methotrexate, MMF
Post-transplant cyclophosphamide
Fludarabine, cyclophosphamide and low dose TBI or other regimens
Unmanipulated BM or PB stem cells
Cyclophosphamide D+3, +4, Calcineurin inhibitor, Short course of MMF

Figure 107.3 COMPONENTS OF EACH TRANSPLANTATION PLATFORM. Interventions on the donor or the recipient for each transplantation platform are shown at each stage of the transplant procedure. *ATG*, Antithymocyte globulin; *BM*, bone marrow; *BMT*, blood or bone marrow transplant; *GCSF*, granulocyte colony-stimulating factor; *GIAC*, granulocyte colony-stimulating factor stimulation of the donor; intensified immunosuppression including cyclosporine A, mycophenolate mofetil, and methotrexate; antithymocyte globulin; and combination of peripheral blood and bone marrow allografts; *G-PBSCs*, granulocyte colony-stimulating factor-mobilized peripheral blood stem cells; *MMF*, mycophenolate mofetil; *PBSCs*, peripheral blood stem cells; *PTCy*, post-transplant cyclophosphamide; *TBI*, total-body irradiation; *TCD*, T-cell depletion; *TCR*, T-cell receptor.

early expansion of T-cell repertoires and improved pathogen-specific responses were observed. Although none of the patients developed CMV-associated disease, NRM still occurred in 13 patients (50%), 8 of whom died of infectious complications. In an updated report on an expanded cohort of patients the authors showed similar results and suggested that, in both mouse models and human studies, the infusion of Tregs appears to control GVHD without affecting graft-versus-tumor immunity.[79] While relapse rates for patients treated in this study appeared better than in historical controls, NRM remained high, particularly death as a result of infection, despite laboratory evidence of improved immune reconstitution post-transplant.

Viral reactivation is a major cause of morbidity and mortality early, especially after TCD haploidentical transplantation, and, in general, a higher number of viral reactivations has been associated with higher NRM.[80] Hence, prevention and early treatment of viral infections post-transplant is crucial for the success of transplantation. Several groups explored infusion of viral-specific cytotoxic T lymphocytes (CTLs) for the prevention or treatment of viral infections early post-transplant.[81] These T cells expand in vivo following infusion and exert antiviral effects without causing GVHD.[81,82] Leen and colleagues showed that CTLs against single or multiple viruses that commonly reactivate post-transplant can be safely infused with evidence of antiviral activity in these patients.[81]

Due to the fact that administration of unmodified CD3+ selected donor lymphocytes early post-transplant carries a major risk of development of acute GVHD, infusion of genetically modified donor lymphocytes expressing a suicide gene that could be activated by administration of ganciclovir if GVHD develops has been explored.[83,84] In a study of 50 patients, the use of this treatment strategy markedly accelerated immune reconstitution.[83] When GVHD did occur, it was promptly and effectively abated by induction of the suicide gene. Although this appeared to be a promising approach, NRM in this study was still high (approximately 40% of the patients). In addition, due to the fact that ganciclovir is a commonly used drug in transplantation for treatment of CMV reactivation, the Baylor group developed an alternative approach using an inducible caspase 9 suicide gene incorporated in donor lymphocytes, which could be eliminated using an inert molecule as dimerizing drug.[84] Administration of this drug resulted in successful elimination of greater than 90% of lymphocytes and promptly stopped the development of GVHD.[84] In a follow-up study, the same group treated 10 haploidentical transplant patients with iCasp9-modified donor lymphocyte infusion (DLI) and showed a favorable effect on immune responses against viral and fungal pathogens.[85] This approach was also studied in conjunction with alpha/beta TCD haploidentical transplantation (see following section), with excellent results.

Alpha/Beta T-Cell Depleted Haploidentical Transplantation

Acute and chronic GVHD reactions associated with a major HLA disparity between the donor and the recipient have been a main concern since the first introduction of haploidentical donor transplantation.[86,87] As previously mentioned, while a full HLA haploidentical graft with conventional GVHD prophylaxis has been associated with unacceptable incidence of GVHD, the use of complete T-cell depletion methods resulted in very high treatment-related mortality.[18,20,21,88] These results have emphasized the beneficial effect of donor T lymphocytes and other immune cells in the graft, and led to the development of novel techniques of graft manipulation with the goal to selectively deplete T-cell subgroups most likely responsible for development of GVHD.

The majority of peripheral blood T cells express αβ T-cell receptor (TCR), while approximately 5% express γδ TCR. It has been shown that a donor-derived αβ T-cell subset plays a major role in the pathogenesis of GVHD, unlike innate-like γδ T cells, which are capable of directly recognizing targets in an MHC-independent manner, enabling them to exert anti-tumor activity by directly identifying stress-induced antigens expressed on malignant cells, without recognition of classical MHC-associated alloantigens.[89–91] Several studies have demonstrated that an increased number of donor-derived γδ T cells following HLA mismatched related allogeneic hematopoietic stem cell transplants is significantly associated with better disease-free survival.[92,93]

Based on these findings, the immunomagnetic method of ex vivo selective depletion of αβ T cells from mobilized peripheral blood grafts has been pioneered by Chaleff and Handgretinger using a biotinylated anti-TCRαβ antibody, followed by an anti-biotin antibody conjugated to magnetic microbeads, which causes approximately 4 log reduction of αβ T cells, while maintaining in the graft the majority of CD34+ cells, as well as the NK cells and γδ T cells.[26,94] Several groups have demonstrated that the efficacy in T-cell reduction using this method was comparable to CD34+ positive selection and more effective than CD3+/CD19+ T-cell depletion, whereas recovery of CD34+ cells after depletion is comparable in all three procedures.[26] In addition, results from animal models of transplantation of αβ+ T-cell depleted graft showed rapid engraftment.[94] This method was subsequently combined with depletion of CD19+ B lymphocytes in order to prevent post-transplant EBV-associated lymphoproliferative disease. In the first clinical experience, 23 pediatric patients with advanced hematologic malignancies treated in Tübingen and Rome received TCRαβ+/CD19+ depleted haploidentical peripheral blood grafts, with either reduced-intensity (melphalan, thiotepa, fludarabine, or clofarabine and OKT-3 or ATG) or myeloablative (fractionated TBI, thiotepa, fludarabine, and ATG) conditioning regimen. All patients achieved sustained engraftment, rapid immune reconstitution, and had low incidence of GVHD, despite that no post-transplant pharmacologic GVHD prophylaxis was administered.[95]

Lang et al. reported in abstract format long-term follow-up results of 60 patients (30 adults, 30 pediatric patients) with malignant and nonmalignant diseases who received TCRαβ+/CD19+ depleted peripheral blood stem cell grafts from haploidentical donors as part of a prospective, multi-center, single-arm, phase I/II clinical trial. All patients received reduced-intensity conditioning (RIC) with fludarabine, melphalan, thiotepa, and either ATG or total nodal irradiation, and a short course of mycophenolate mofetil for GVHD prophylaxis. Rapid engraftment was observed with median time to neutrophil and platelet engraftment of 13 and 15 days, respectively. Eight of nine patients who had graft rejection were successfully re-transplanted. None of the patients developed severe acute GVHD, while severe chronic GVHD occurred in only 9%. However, a higher rate of viral reactivation was observed, with three patients dying of adenovirus disease. At 2-year follow-up, OS and DFS were 62% and 53%, respectively, while cumulative incidences of relapse and NRM were 34% and 20%, respectively.[96] Similarly, successful engraftment and lower rate of GVHD have been confirmed in several studies, both in pediatric and adult patients.[97–101]

Post-transplant immunologic recovery has also been investigated after TCRαβ+/CD19+ depleted haploidentical transplantation. Results from an immunologic reconstitution study of 41 recipients of TCRαβ+/CD19+ depleted haploidentical transplantation showed a significantly higher number of CD3+, CD3+CD4+, and CD56+ cells early post-transplant compared to a historical control group of 36 pediatric patients receiving positive CD34+ selected haploidentical stem cells. In this study, recovery of γδ T cells started at day +7 post-transplant and preceded αβ T-cell reconstitution.[99] Airoldi and colleagues found that γδ T cells are the predominant T-cell population in patients during the first weeks after transplantation, derived not only from cells infused with the graft but also γδ T cells differentiated from donor's hematopoietic stem cells.[32]

Not only has a rapid increase in number of donor-derived immunologic cell subsets post-transplant been observed, but these cells also might provide a benefit in graft-versus-tumor effect, as evidenced in several studies. Focusing on pediatric patients with acute leukemia, Locatelli et al. reported outcomes of 80 patients of TCRαβ+/CD19+ depleted haploidentical transplant using myeloablative conditioning without post-transplant GVHD prophylaxis, and showed a high GVHD-free, relapse-free survival (GRFS) of 71% at 5 years, comparable to those of children given transplantation from an HLA-identical sibling or a 10/10 MUD treated during the same period of time.[100] Similar results were also reported in other studies, in both pediatric and adult patients with high-risk leukemias.[101–103]

The benefit of lower incidence of GVHD in TCRαβ+/CD19+ depleted haploidentical transplants may be more important for patients with non-malignant diseases. A prospective study conducted in 23 pediatric patients with non-malignant diseases treated with TCRαβ+/CD19+ depleted haploidentical transplants showed promising outcomes with high engraftment rate and very low incidence of both acute and chronic GVHD. In this study, the cumulative incidence of grade I–II aGVHD was only 13.1%, no chronic GVHD was observed, and transplant-related mortality was only 9%. With a median follow-up of 18 months, 21 of 23 children were alive and disease-free with the 2-year probability of disease-free survival of 91.1%. Considering both primary and secondary graft failure as events, the probability of EFS was 74%.[98] Another study of 14 pediatric patients with thalassemia also reported a high rate of engraftment. In this study the cumulative incidence of engraftment failure was 14%, significantly lower than a historical group of 40 patients with hemoglobinopathies who received CD34+ selected haploidentical grafts (45%). Overall survival and disease-free survival were 78% and 69%, respectively. However, a higher incidence of GVHD was observed in this study despite receiving post-transplant pharmacological prophylaxis up to 60 days (with 28% incidence of grade II–III acute GVHD and 21% chronic extensive GVHD), and viral reactivations, such as CMV, ADV, and BKV, were also common.[104] Although the number of patients treated so far is relatively small and no definitive conclusions can be drawn, it is important to notice that a higher incidence of GVHD has also been seen in adults receiving TCRαβ+/CD19+ depleted haploidentical transplantation in some studies.[105]

Taken together, current available data indicate that TCRαβ+/CD19+ depleted haploidentical transplantation can provide an alternative option for patients without an HLA-matched donor with several studies that reported outcomes comparable to HLA-matched related or unrelated donor transplants.[99,100,102,106] Moreover, the low risk of GVHD without the need of long-term post-transplant immunosuppression may provide a better opportunity to apply cellular therapy post-transplant and help improve quality of life, which could make this type of haploidentical transplant more appealing, especially for pediatric patients. Novel pharmacologic and adoptive cellular therapy approaches to enhance anti-tumor effect and immune reconstitution and improve outcomes after TCRαβ+/CD19+ depleted haploidentical transplantation are being investigated.

G-CSF Stimulation of the Donor, Intensified Immunosuppression (CsA, MMF, and MTX), Anti-Thymocyte Globulin; and Combination of Peripheral Blood and Bone Marrow Allografts ("GIAC" Protocol)

Treatment of bone marrow donors with G-CSF before donation increases marrow CD34$^+$ cells and granulocyte-macrophage colony-forming units, reduces total lymphocytes, and reverses the CD4$^+$/CD8$^+$ T-cell ratio. To enhance engraftment by increasing the dose of transplanted HSCs, 15 patients with high-risk leukemia received myeloablative conditioning with cytarabine, cyclophosphamide, and 1000 cGy TBI, and G-CSF–primed bone marrow from haploidentical donors. GVHD prophylaxis consisted of rabbit ATG (5 mg/kg/day on days −4 through −1), cyclosporine (CsA), methotrexate, and mycophenolate mofetil (MMF).[107] At the time of reporting, all 15 patients had prompt trilineage hematopoietic engraftment; the cumulative incidence of GVHD was 33%; and 9 of 15 patients were alive at a median follow-up of 22 months (range, 13 to 35 months). Subsequently, Lu et al. compared outcomes of 293 patients with leukemia receiving HLA-matched sibling ($n = 158$) or

HLA-haploidentical related grafts ($n = 135$) from G-CSF–primed donors.[108] Patients undergoing haploidentical SCT were conditioned with cytarabine, oral busulfan, cyclophosphamide, and methyl-CCNU (1-[2-chloroethyl]-3-[4-methylcyclohexyl]-1-nitrosourea), received G-CSF primed bone marrow on day 0 ($n = 134$) and/or G-CSF–primed peripheral blood on day 1 ($n = 131$), and GVHD prophylaxis with ATG 2.5 mg/kg/day on days −4 through −1, CsA, MTX, and MMF. All but two haploidentical SCT patients treated with the GIAC protocol had sustained engraftment of donor neutrophils. The cumulative incidence of acute grades II–IV, grades III–IV, and chronic GVHD in recipients of matched versus mismatched SCT were 32% versus 40% ($P = .13$), 11% versus 16%, and 56% versus 55%. Mismatched patients had a higher incidence of CMV antigenemia (65% vs. 39%; $P < .001$) and hemorrhagic cystitis (35% vs. 13%; $P < .001$), but not of CMV disease. Two-year relapse rate was 13% versus 18% ($P = .40$), NRM 14% versus 22% ($P = .10$), LFS 71% versus 64%, and OS 72% versus 71% ($P = .72$), in the matched and mismatched cohorts, respectively. In a follow-up report of 157 recipients treated with this approach, recipients of CD3$^+$ T-cell doses higher than the median (1.77×10^8/kg) had a significantly lower NRM, better LFS, and better OS.[109] Two other Chinese groups reported similar results of retrospective studies comparing outcomes of patients who received haploSCT with those of patients who received HLA-matched sibling or HLA-matched unrelated transplants.[110,111] Moreover, in a prospective, multicenter study comparing haploSCT ($n = 231$) versus HLA-matched sibling transplants ($n = 219$) using biologic randomization based on donor availability, similar outcomes were noted between the two groups.[112]

Although outcomes are in general very good (especially because patients treated are up to age 60) a higher proportion of patients develop severe acute and mostly chronic GVHD. Several groups have attempted to reduce the incidence of GVHD seen with this protocol.[113–116] In a Korean study in which a modified version of this platform was used with RIC and only G-CSF mobilized PBSC allografts, authors showed a lower incidence of grades II–IV acute (20%) and chronic (34%) GVHD.[113] A different group modified this protocol to use TBI-based conditioning, only GCSF-primed bone marrow, and added basiliximab to enhance GVHD prophylaxis.[114,115] Although this approach resulted in lower incidence of grades II–IV acute GVHD of 11%, chronic GVHD was still seen in most patients, yet was mostly limited in severity. The Rome Transplant Network employed the same GVHD prophylaxis and reported in 97 patients encouraging results in terms of GVHD control (grades II–IV and grades III–IV acute GVHD of 31% and 9%, respectively, and extensive chronic GVHD of 12%); however, 1-year NRM was 32%.[116]

Survival outcomes of patients with acute leukemia receiving haploSCT with this protocol have been particularly encouraging, owing primarily to lower incidence of relapse in the haploidentical versus HLA matched group (26% vs. 49%; $P = .008$).[33] In 2009, the Peking University group reported the results of a study of 250 consecutively treated patients with acute leukemia, 108 of whom had AML and 142 of whom had ALL.[117] Survival of patients with AML were particularly favorable, with 3-year OS of 73% and 56% reported for standard-risk and high-risk groups, respectively.[112] However, outcomes of patients with high-risk ALL appeared poor because of higher incidence of NRM (51%) and relapse (49%) at 3 years, presumably due to intense myeloablative conditioning, usually less well tolerated in this group of patients.[117]. Patients with standard-risk ALL, however, had 3-year OS of 60%.[117] Two other studies have confirmed excellent survival of patients with ALL in CR1 treated with haploSCT using this protocol.[112,118] In another ALL study,[119] patients received consolidation with either 2 years of chemotherapy ($n = 104$) or haploSCT ($n = 79$) (as preferred by the patients); those who received haploSCT had markedly better 3-year disease-free survival (DFS) (64% vs. 21%), OS (72% vs. 27%), due to a much lower cumulative incidence of relapse (19% vs. 61%) compared with chemotherapy-treated patients.[119] In multivariate analyses, consolidation of remission with a haploSCT was the only factor associated with lower relapse and better OS in these patients.

In all these studies, the extent of HLA disparity did not affect survival post-transplant.[110,120,121] However, donor characteristics appeared to impact patient outcomes; lowest NRM and best survival were seen with younger, male donors, and lower incidence of acute GVHD occurred when the donor was the patient's child or an HLA-haploidentical relative who was mismatched for non-inherited maternal HLA antigens (NIMA), while the use of maternal donors was associated with higher incidence of acute and chronic GVHD, and worse survival.[121]

A few studies compared outcomes of unmanipulated haploSCT using the GIAC protocol with post-transplantation cyclophosphamide approach and will be discussed later in this chapter.

Haploidentical Transplantation With Post-Transplant Cyclophosphamide

The effects of cyclophosphamide (Cy), one of the oldest chemotherapeutic agents, have been studied since the early 1960s.[122] High-dose Cy was found to be effective in prolonging the survival of MHC-mismatched mouse skin allografts only when the drug was given up to the fourth day post-transplant, with the optimal effectiveness of this treatment being at 2 days post-transplant.[123] This work was continued by a number of groups into the mid-1990s, which investigated mechanisms of tolerance induction by Cy.[124,125] By administering donor spleen cells followed 48 to 72 hours later by administration of cyclophosphamide, long-lasting tolerance to MHC-compatible, but not MHC-incompatible, skin allografts was established. Three primary mechanisms of post-transplant cyclophosphamide (PTCy)-induced tolerance were identified in this model: (1) Direct elimination of host T cells responding to donor antigens in the periphery, (2) intra-thymic clonal deletion of donor-reactive host T cells, and (3) generation of tolerogen-specific host suppressor T cells.[126] Suppressor T cells were found to inhibit responses to both major and minor histocompatibility antigens through active suppression but not clonal deletion of alloreactive T cells.[127] Induction of tolerance by PTCy was disrupted by the administration of CsA or corticosteroids before adoptive cell transfer and cyclophosphamide treatment,[128,129] while it was not affected by the administration of G-CSF starting the day after PTCy treatment.[130]

PTCy found its greatest applicability in haploidentical transplantation. In the initial experiments in MHC-mismatched mouse models, treatment with PTCy reduced the dose of radiation required to induce reliable engraftment,[131] prevented GVHD, and prolonged survival.[27] Graft failure could be further reduced by the use of antilymphocyte globulin,[132] and radiation in the conditioning regimen could be replaced, at least in part by fludarabine, although high levels of donor chimerism required at least 100 cGy of TBI.[27] The resultant mixed chimeras were tolerant to both donor and host but maintained reactivity against third-party alloantigens in mixed lymphocyte culture.[27,131,132] This tolerogenic effect allowed skin and heart allografts from the MHC-mismatched donor strain to survive, whereas MHC-disparate third-party grafts were rejected.[131,133]

Parallel to the effects seen on host T cells in skin allograft models, in transplant mouse models, treatment with PTCy inhibited GVHD through elimination of alloreactive donor T cells.[134] Donor T cells exposed to antigen on day 0 were largely depleted by PTCy, whereas non-alloreactive donor T cells, which divided more slowly in a lymphopenic environment, were relatively spared (Fig. 107.4).[134] However, elimination of alloreactive donor T cells was necessary but not sufficient for PTCy-induced tolerance. The role of Tregs in inducing, as opposed to maintaining, tolerance is controversial. In mouse models of MHC-matched transplants in which donor CD4$^+$ T cells promote GVHD, donor Tregs were necessary to prevent lethal GVHD after PTCy treatment,[135,136] an effect consistent with the results from skin allograft models. In mouse models as well as human studies, donor Tregs were resistant to PTCy-induced cytotoxicity, owing to increased expression of aldehyde dehydrogenase, the enzyme primarily responsible for in vivo detoxification of cyclophosphamide.[135–137] In contrast, PTCy can induce tolerance in alloreactive CD8$^+$ T cells in the absence of CD4$^+$ T cells, including CD4$^+$ Tregs.[135] In

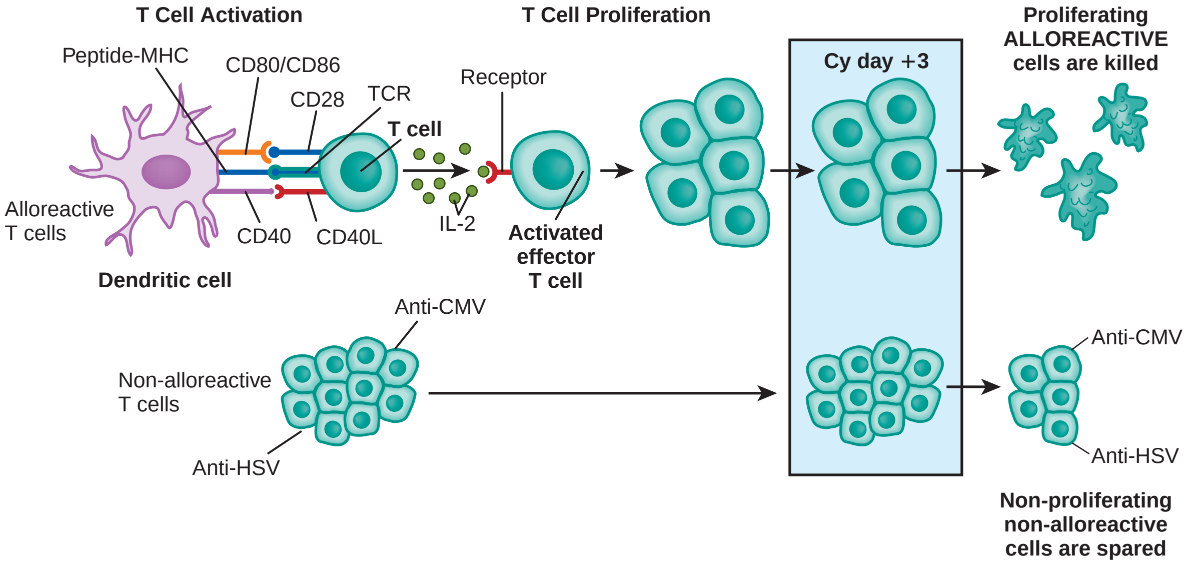


Figure 107.4 CYCLOPHOSPHAMIDE-INDUCED TOLERANCE TO HISTOCOMPATIBILITY ANTIGENS. On the day of transplant, alloreactive donor and host T cells encounter alloantigen on the surface of host and donor antigen-presenting cells, which also provide costimulatory ligands for T-cell activation *(top left)*. The alloreactive T cells secrete cytokines such as interleukin (IL)-2 and proliferate. Because cyclophosphamide is more toxic to proliferating than to resting cells, the drug induces substantial killing of the alloreactive population while relatively sparing the resting, nonalloreactive T cells, including cells responsible for immunity to pathogens *(bottom)*. Thus this protocol provides for selective allodepletion of alloreactive T cells while permitting a more rapid immune reconstitution compared with complete depletion of T cells from the graft. *CMV*, Cytomegalovirus; *HSV*, herpes simplex virus; *MHC*, major histocompatibility complex; *TCR*, T-cell receptor.

addition, other studies have shown that Tregs are not required for cyclophosphamide-induced tolerance of tumor-reactive T cells[138] or for transplant tolerance induced by a different alkylating agent, bendamustine.[139]

Clinical Studies Using Post-Transplant Cyclophosphamide-Based Graft-Versus-Host Disease Prophylaxis

In an initial phase I clinical trial of 13 patients done at John Hopkins, patients received a non-myeloablative (NMA) conditioning regimen with fludarabine ± cyclophosphamide and low-dose (200 cGy) TBI, a T-cell replete haploidentical bone marrow graft, and one dose of PTCy 50 mg/kg on day +3 post-transplant.[140] For GVHD prophylaxis, in addition to tacrolimus, MMF was also added starting the day after patients received PTCy and continued for at least 30 days. Approximately 80% of patients who had fludarabine, cyclophosphamide, and 2GyTBI successfully engrafted, and half the patients were alive and in remission after a median follow-up of 284 days. Grade II–IV acute GVHD developed in 6 patients. Application of two doses of cyclophosphamide was found to be more effective in facilitating engraftment and in preventing GVHD. Subsequently, a phase I/II study performed at two institutions enrolled 68 patients,[141] and the majority received two doses of PTCy on day +3 and +4 post-post-transplant. Eighty-seven percent of patients engrafted and achieved complete or near-complete donor chimerism by 1 to 2 months post-transplant. Grades II–IV and grades III–IV acute GVHD occurred in 34% and 6% of patients, respectively. The incidence of extensive chronic GVHD was very low, significantly lower in patients receiving two doses of PTCy (5%). Longer follow-up of an expanded cohort of 210 patients treated according to the JHH protocol confirmed very low incidence of NRM, acute GVHD, and chronic GVHD.[142] The extent of HLA disparity had no negative effects on acute GVHD or progression-free survival (PFS).[143] In addition, a relatively high rate of relapse (55%) was observed, in part reflected by the use of NMA conditioning in patients with acute leukemia and by the advanced disease state of patients who received transplants. Interestingly, a disease risk–stratified analysis of 372 patients performed by the Johns Hopkins group showed that survival outcomes were comparable with those of patients receiving HLA-matched allogeneic stem cell transplantation.[144]

Nevertheless, in an effort to reduce relapse rates post-transplant, several groups explored intensified conditioning with either a melphalan-, total body irradiation (TBI)-, thiotepa-, or busulfan-based regimen for haploidentical transplants in the adult and pediatric population.[28–30,145,146] These studies showed, in general, higher NRM (3% to 21%) lower incidence of relapse (19% to 35%), comparable incidence of grades II–IV aGVHD (12% to 30%), III–IV aGVHD (3% to 10%), and cGVHD (10% to 26%), and at least as good survival as NMA conditioning (1-year DFS 51% to 70%). It is now generally accepted that, as in HLA matched transplants,[147] younger, fit patients with acute leukemia should receive a myeloablative conditioning regimen, while older, less fit individuals and lymphoma patients should be treated with a RIC/NMA conditioning regimen.[148,149] A summary of commonly employed conditioning regimens for haploSCT with PTCy-based GVHD prophylaxis is presented in Table 107.1.

An alternative two-step approach to myeloablative PTCy haploSCT separates the induction of tolerance to donor cells (step 1) from hematopoietic rescue (step 2). Patients received a TBI-based conditioning and peripheral blood T cells at a fixed dose on pre-transplantation day −6, two doses of cyclophosphamide 60 mg/kg/day on days −3 and −2 for tolerance induction (step 1), followed by a CD34-selected PBSC graft from the same donor on day 0.[150,151] This procedure mimicked the timing of the standard PTCy platform, except that stem cells were spared exposure to cyclophosphamide. Although there were concerns initially with exposure of stem cells to cyclophosphamide, no detrimental effects have been observed long term, now after greater than 10 years of application of Cy in haploSCT. Results for patients who were in remission at the time of transplant showed a low incidence of grades III–IV acute (4%) and chronic (21%) GVHD, NRM of 3.6%, and relapse-related mortality of 19%, leading to a 2-year DFS of 74%.

Although initially a bone marrow graft was used almost exclusively for haploidentical transplantation, several groups have explored the use of peripheral blood stem cells (PBSCs) for haploidentical transplantation with PTCy,[28,152–154] and several studies compared these two donor sources for haploidentical transplantation.[154–157] As seen in a randomized study conducted by the Blood and Marrow Transplant Clinical Trials Network (BMTCTN) in unrelated donor

transplantation,[158] the use of peripheral blood graft has been, in general, associated with a slightly higher engraftment rate yet a higher incidence of acute and chronic GVHD, with similar survival in most studies, including in a recent meta-analysis.[155–157,159] However, for patients with acute lymphoblastic leukemia, a bone marrow graft should be preferred as it was associated with lower incidence of GVHD and NRM and better DFS and GRFS survival in a European Blood and Marrow Transplant (EBMT) analysis.[160]

Post-Transplant Cyclophosphamide in Combined Solid Organ—Hematopoietic Stem Cell Transplantation

PTCy has shown promise as a tolerizing agent in facilitating mismatched hematopoietic stem cell grafts infused during or soon after solid-organ transplantation with the goal to achieve complete tolerance of the solid organ grafts. Leventhal et al. reported on combined kidney and hematopoietic transplants in which fludarabine/cyclophosphamide conditioning was administered before renal transplant and column-selected PBSCs were given the day after renal transplant.[161–163] Mycophenolate and tacrolimus were started 2 days before kidney transplant and one dose of PTCy (50 mg/kg) was given 3 days post-transplant. According to the latest report, 12 of 19 patients[163] achieved functional tolerance after full donor chimerism as demonstrated by successful cessation of all immunosuppression without graft rejection. This approach suggests that tolerance induction in solid organ transplantation appears to be dependent on achieving sustained donor chimerism.[162] Future studies will explore the use of haploSCT with PTCy after solid organ transplantation to achieve complete tolerance of the transplanted organ to the recipient's immune system.

COMPARATIVE OUTCOMES BETWEEN HAPLOIDENTICAL AND OTHER DONOR GRAFTS

With multiple platforms being developed for patients receiving haploidentical transplantation, the natural question is how outcomes of haploidentical transplants using different approaches compare, and how outcomes of haploidentical transplants compare with other donor types. Only a few studies to date have retrospectively compared outcomes using different haploidentical transplantation platforms. In an initial retrospective study of 65 adult patients receiving haploSCT using either PTCy or megadose T-cell–depleted stem cells for GVHD prophylaxis, survival was significantly better for patients receiving PTCy.[19] NRM was markedly lower after TCR graft and PTCy-based GVHD prophylaxis versus TCD haploidentical transplantation (16% vs. 42% at 1 year), with the difference largely a result of lower risk of viral (twofold lower) and fungal (fivefold lower) infections post-transplant. A more rapid immunologic reconstitution was noted in patients receiving PTCy, with similar incidence of aGVHD, lower incidence of cGVHD (7% vs. 18%), similar relapse rate post-transplant, and significantly better survival (64% vs. 30%, $P = .02$).[19]

Another study compared haploidentical transplants performed with PTCy and GIAC protocol (anti-thymocyte globulin [ATG]) for patients with AML.[164] Patients in the PTCy group ($n = 193$) had significantly less severe (grades III–IV) aGVHD than patients in the GIAC group ($n = 115$), 5% versus 12%, respectively ($P = .01$), with similar incidence of chronic GVHD and relapse incidence. However, recipients of PTCy had a significantly lower incidence of NRM (22% vs. 30%; $P = .02$) and improved LFS (HR, 1.48; 95% CI, 1.03 to 2.12; $P = .03$). Taken together, these results suggest that TCR haploSCT with PTCy may the best haploidentical transplant platform to date, yet additional studies are needed, including comparing PTCy with αβTCD.

As noted earlier in this chapter, traditional donor choices in patients receiving conventional GVHD prophylaxis relied on HLA matched donors, as outcomes with haploidentical donors were associated with unacceptable toxicity. HLA-matched sibling donors were preferred, as they were associated with the best outcomes. If an HLA-matched sibling donor was not available, the preferred donor was a well-matched (at least 8/8 allele match at HLA-A, HLA-B, HLA-C, HLA-DRB1) MUD and, in the absence of an HLA-matched sibling or MUD, the choices may be a partially HLA-matched unrelated donor, an unrelated umbilical cord blood, and an HLA-haploidentical first-degree relative. The introduction of PTCy for GVHD prophylaxis has significantly improved transplant outcomes with haploidentical donors, now similar at least with MUDs, and raised questions whether traditional donor choice should continue be used, or if other factors should be considered such as urgency to transplantation.[3] Multiple studies, mostly retrospective, compared outcomes of haploidentical transplants with PTCy with other donor sources; the most relevant are summarized below.

Haploidentical Versus Cord Blood Transplants

The Acute Leukemia Working Party of the EBMT group compared outcomes after UCBT and haploSCT in adults with de novo AML ($n = 918$, comprising 360 haploSCT, 558 UCBT) and ALL ($n = 528$, comprising 158 haploSCT, 370 UCBT).[165] Conditioning regimens were a mixture of myeloablative and RIC, and GVHD prophylaxis for recipients of haplo transplants included PTCy in 163, ATG in 244, and neither ATG nor PTCy in 111 patients. UCBT was associated with delayed engraftment and a higher incidence of graft failure, but a lower incidence of chronic GVHD, for both AML and ALL patients. There were no significant differences between graft sources in the incidence of NRM or relapse or in LFS. The authors concluded that both haplo and UCBT grafts are acceptable approaches for patients with acute leukemia lacking an HLA-matched donor.[165] However, the main limitation of this study was that it included haploidentical transplants performed with methods other than PTCy, which have been associated with worse outcomes.[166,167]

The Blood and Marrow Transplant Clinical Trials Network (BMT CTN) in the United States conducted two prospective parallel trials of RIC followed by either double-UCBT (dUCBT) (BMT CTN 0604) or haploSCT with PTCy for patients with acute leukemia or lymphoma.[168,169] The 100-day cumulative incidence of grades II–IV acute GVHD was 40% after dUCBT and 32% after haploSCT. The 1-year cumulative incidence rates of NRM and relapse after dUCBT transplant were 24% and 31%, respectively, with corresponding results of 7% and 45% after haploSCT. OS and PFS were 39% (95% CI, 26% to 53%) and 36% (95% CI, 23% to 49%), respectively, after dUCBT and 54% (95% CI, 39% to 67%) and 35% (95% CI, 21% to 48%), respectively, after haploSCT. The similar PFS seen in these two trials provided equipoise for the multicenter randomized phase III BMT CTN trial (ClinicalTrials.gov identifier NCT01597778) comparing these two different graft sources after RIC. Outcomes from this study were recently reported.[170] Three hundred sixty-eight patients (18 to 70 years old) with leukemia and lymphoma were randomized to receive either a cord blood transplant ($n = 186$) or a haploidentical donor transplant ($n = 182$) with a similar conditioning regimen including fludarabine, cyclophosphamide, and 2Gy TBI. The primary endpoint was PFS, and all outcomes reported are at 2 years. The PFS was 35% versus 41% ($P = .41$) in favor of haploSCT, NRM was higher in the CBT, 18% versus 11% ($P = .04$) and OS was 46% versus 57% ($P = .04$), respectively. This study confirmed lower NRM and better survival with haploidentical donor transplants, and suggested that a haploidentical donor, when available, should be preferred to a double umbilical cord blood transplant.[170]

Several other large retrospective studies compared outcomes between haploidentical donor transplants and UCBT for different diseases and showed, in general, better outcomes with haploSCT.[171–174]

Haploidentical Versus Human Leukocyte Antigen Matched and Mismatched Unrelated Donor Transplants

GIAC Protocol

The Beijing group and the EBMT conducted a retrospective comparison of patients with AML and intermediate-risk cytogenetics receiving haploidentical transplants using the GIAC protocol ($n = 87$) versus control subjects receiving fully matched (10/10) URD transplants ($n = 87$).[175] Cases and control subjects were matched for age ±5 years, interval from CR1 to transplant, and the number of induction courses required to achieve CR1. Outcomes were similar in both groups: the 5-year LFS was 60.3% in the URD group versus 73.5% in the haplo group ($P = .15$), OS was 63.6% versus 78.2% ($P = .15$), relapse incidence was 24% versus 12.7% ($P = .08$), and NRM was 15.7% versus 13.8% ($P = .96$).[175]

α/β T-Cell Depleted Haploidentical Transplantation

α/β T-cell/B-cell depleted haploSCT in children has been compared with HLA matched and mismatched unrelated donor transplantation. Outcomes of 98 patients receiving haploSCT, 127 MUD, and 118 mismatched MUD (MMUD) were compared in a multicenter retrospective study.[106] Recipients of haploSCT had significantly lower incidence of grade II–IV and III–IV aGVHD (16% and 0% vs. 35% and 47% for MUD, $P < .001$) and chronic GVHD, and 5-year LFS of 62% versus 67% and 55% respectively ($P < .001$) with no significant differences in LFS and GRFS between MUD and α/β T-cell/B-cell depleted haploSCT.[106]

Post-Transplant Cyclophosphamide

Multiple retrospective studies compared outcomes of haploSCT with PTCy with MUD transplants. Two CIBMTR studies compared outcomes of MUD transplants with those of haploSCT with PTCy for patients with AML[176] as well as for patients with lymphoma.[177] For patients with AML receiving MAC, haploidentical transplants had a lower incidence of grade II–IV aGVHD (16 vs. 33%; $P < .0001$) and 3-year chronic GVHD (30% vs. 53%; $P < .0001$). Similar differences in GVHD were also seen after RIC/NMA conditioning. Three-year probability of OS after myeloablative conditioning was 45% after haploSCT versus 50% after MUD transplants ($P = .38$), while the corresponding rates after RIC were 46% for haplo and 44% for MUD transplants ($P = .71$).[176]

A similar study evaluated outcomes of patients with lymphoma receiving RIC and compared three groups: haploidentical transplants with PTCy versus MUD transplants, without and with ATG. The 1-year cumulative incidence rates of chronic GVHD were 13%, 51%, and 33%, respectively ($P < .001$). In multivariate analysis, incidence of grade III–IV aGVHD was higher in MUD without ATG ($P = .001$), as well as MUD with ATG ($P = .01$), relative to haploidentical transplants. Cumulative incidence rates of relapse at 3 years were 36%, 28%, and 36% in the haploidentical, MUD without ATG, and MUD with ATG groups, respectively ($P = .07$), and the corresponding 3-year OS rates were 60%, 62%, and 50%, respectively, in the three groups, with multivariate analysis showing no

TABLE 107.2 Selected Retrospective Registry Studies Comparing Outcomes of Haploidentical Transplants With Post-Transplant Cyclophosphamide With Matched Unrelated Donor Transplants

Disease Subtype	N	aGVHD	cGVHD	TRM	Relapse	3-Year PFS	GRFS
AML[176]

[a] Two-year survival is reported.
[b] Haploidentical recipients were matched (1:2) with MUD controls.
aGVHD, Acute graft-versus-host disease; *ALL*, acute lymphoblastic leukemia; *AML*, acute myeloid leukemia; cGVHD, chronic graft-versus-host disease; *DLBCL*, diffuse large B-cell lymphoma; *GRFS*, GVHD-free, relapse-free survival; *HaploSCT*, allogeneic hematopoietic stem cell transplantation; *MAC*, myeloablative conditioning; *MUD*, matched unrelated donors; *NRM*, non-relapse mortality; *PFS*, progression-free survival; *RIC*, reduced intensity conditioning; *TCD*, T-cell depletion.

survival difference between MUD without ATG ($P = .21$) relative to haploidentical transplants and significantly worse compared with MUD with ATG. These data demonstrated that, for patients with lymphoma, haploidentical transplants with PTCy produce survival outcomes as good as those seen after transplants using MUD transplants without ATG, with much less cGVHD, which could translate into a long-term survival benefit. A follow-up study is thus needed to appreciate long-term survival between these groups.

Other important registry studies compared outcomes between haploidentical, MUD ± MSD transplants and yielded similar results between haploSCT and matched transplants across many diseases including lymphoma[178–180] and acute lymphoblastic leukemia (Table 107.2).[181,182]

Haploidentical Versus Human Leukocyte Antigen-Matched Sibling Donor Transplants

Encouraging outcomes between haploidentical and unrelated donor transplants prompted comparisons between haploidentical donor transplant and MSD transplants for patients with hematological malignancies and different diseases. Part of these studies have been detailed above.

GIAC Protocol

Using the GIAC protocol, the Beijing group performed several single-center, nonrandomized studies which suggested that survival after haploidentical transplants using the GIAC protocol was similar with HLA-matched sibling donor transplants.[108,111] These studies motivated a prospective, multicenter trial with biologic assignment, in which patients with AML in CR1 were assigned to receive a transplant after myeloablative conditioning from an HLA-matched sibling ($n = 219$) or, if a matched sibling was not available, an HLA-haploidentical donor ($n = 231$).[183] Although patients receiving haplo grafts had significantly higher incidence of grades II–IV acute GVHD (36% vs. 13%; $P < .001$), grades III–IV acute GVHD (10% vs. 3%; $P = .004$), and chronic GVHD (42% vs. 15%; $P < .001$) than patients receiving grafts from matched siblings, there were no significant differences between the two groups in 3-year incidence of relapse (15% vs. 15%; $P = .98$), NRM (13% vs. 8%; $P = .13$), DFS (74% vs. 78%; $P = .34$), or OS (79% vs. 82%; $P = .36$) between the two groups.[183]

Post-transplant Cyclophosphamide

A variety of single center reports have retrospectively analyzed the outcomes of transplants from either matched siblings or haploidentical first-degree relatives.[31,184–186] Bashey et al.[185] reported that patients treated with haploSCT with PTCy had very similar outcomes with MUD and MSD transplants except higher 2-year overall survival (57% vs. 59% vs. 72%, $P = .004$) with similar PFS between all 3 groups (54% vs. 50% vs. 56%, $P =$ NS) and lower incidence of moderate to severe cGVHD in favor of haploidentical transplants (31% vs. 47% vs. 44%, $P = .004$). Several other studies showed similar survival after haploSCT, and two studies[185,186] showed a significantly lower incidence of chronic GVHD.

The CIBMTR recently compared outcomes of patients with lymphoma undergoing RIC followed by either HLA-matched sibling SCT ($n = 807$) or haploSCT with PTCy as part of GVHD prophylaxis ($n = 180$).[187] Although platelet recovery was delayed among those treated with haploSCT plus PTCy, the cumulative incidence of chronic GVHD was again significantly lower after haploSCT (12% vs. 45%; $P < .001$), and there were no significant differences between haploSCT and MSD SCT in 3-year NRM (15% vs. 13%; $P = .41$), relapse (37% vs. 40%; $P = .51$), PFS (48% vs. 48%; $P = .96$), or OS (61% vs. 62%; $P = .82$). Another retrospective study performed by CIBMTR evaluated outcomes of donor-recipient pairs in younger (<55 years) or older (±55 years) recipients with acute leukemia receiving an MSD or haploidentical donor transplant and found that, in younger individuals, the 2-year DFS was identical (61% vs. 61%) for patients receiving a haploidentical versus a MSD transplant, while for older individuals, 2-year DFS was better using a MSD versus haploidentical donor (51% vs. 44%) due to a higher NRM in the haplo group, yet lower cGVHD was again observed in the haploidentical versus MSD groups.[188]

These remarkable results in patients receiving a haploSCT with PTCy-based GVHD prophylaxis with similar survival compared with HLA matched transplants yet lower incidence of acute and mostly cGVHD prompted a shift toward adoption of this method of GVHD prophylaxis for HLA matched transplants. A recent study from EBMT compared outcomes between haploidentical with bone marrow graft and MUD transplants with peripheral blood graft for patients with acute leukemia using the same PTCy-based GVHD prophylaxis, and found that, despite the fact that the haploidentical group had lower incidence of acute GVHD (grade II–IV 19.4% vs. 29.7%, $P = .01$; grade III–IV 6.5% vs. 9.2%, $P = .27$) and chronic GVHD (overall 28.9% vs. 39.1%, $P = .058$, and extensive 8.6% vs. 21.1%, $P = .001$), there were no survival differences between the haploidentical and MUD groups at 2-year for DFS (58% vs 61.9 %, $P = .18$), OS (65.4% vs. 64.2%, $P = .67$) and GRFS (54% vs. 44.1%, $P = .45$), respectively.[189]

POTENTIAL COMPLICATIONS AFTER HAPLOIDENTICAL TRANSPLANTATION

HaploSCT with PTCy has generally been well tolerated, yet several potential complications can occur. Some of these complications are characteristic of allogeneic stem cell transplantation in general, such as toxicity from chemotherapy or the development of GVHD, while others are more particular or have a higher incidence with this type of transplant, due to higher HLA disparity between the donor and recipient, such as higher risk of engraftment failure, in part due to risk of development of donor-specific anti-HLA antibodies (DSA), development of CRS in the first few days after haploidentical transplant, especially with a peripheral blood stem cell graft, a higher risk of viral reactivation early post-transplant (CMV, HHV6, BK virus), development of hemorrhagic cystitis (most commonly related to BK virus, more rarely related to cyclophosphamide), and relapse post-transplant. Notably, Epstein-Barr virus–related post-transplant lymphoproliferative disease within the first-year post-transplant is very rare (not seen in a study of 785 patients treated with PTCy),[190] and no increase in donor-derived malignancies was detected after large number of patients received PTCy to date.[191]

The following section details several potential complications after haploidentical transplantation and mitigating strategies.

Graft Failure

Successful donor hematopoietic cell engraftment is the first important step toward the ultimate goal of allogeneic hematopoietic stem cell transplantation to cure the malignant disease, restore normal hematopoiesis and donor immune system to provide beneficial graft-versus-tumor effect. Patients with engraftment failure, either primary, defined as absence of donor hematopoiesis within 28 days post-transplant (or 42 days after UCBT), or secondary, defined as loss of donor hematopoiesis after initial engraftment, can suffer from protracted pancytopenia, risk of fatal infections, and major bleeding in the absence of a second transplant, particularly with more intense conditioning (myeloablative) where autologous hematopoietic reconstitution rarely occurs.

The incidence of graft failure varies significantly in different transplant settings. Several factors are known to be associated with the risk of graft failure, such as older recipient age, highly alloimmunized recipients, greater degree of donor-recipient HLA disparity, major ABO incompatibility, use of nonmyeloablative conditioning, bone marrow stem cell graft, or T-cell depleted graft.[192,193] In contemporary haploidentical stem cell transplantation, the reported incidence of graft failure is up to 10%; however, it can be up to 20% in recipients of T-cell depleted haploidentical transplants.[19,99,106,194] The incidence of engraftment failure has been improved with the use of high-dose post-transplant cyclophosphamide, in part because of more effective elimination of residual host T cells. In addition, the recognition of donor-specific anti-HLA antibodies (DSA) as a major cause of engraftment failure, especially in haploidentical stem cell transplantation, has contributed to lower incidence of engraftment failure in this type of transplant.[48,49,195,196]

The main mechanism of primary graft failure is recipient immunologic reaction against donor cells,[197] mediated primarily by residual host T and NK cells that survived the preparative chemotherapy.[198,199] This mechanism of graft rejection is more important in major HLA mismatched transplants, making haploidentical stem cell transplant recipients more susceptible to develop graft rejection compared to HLA matched donor transplants. Nonetheless, recipients of HLA matched transplants are also at risk of developing T-cell-mediated graft rejection as a result of responses directed against minor histocompatibility antigens.[198]

While the use of myeloablative preparative chemotherapy as well as high-dose post-transplant cyclophosphamide in haploidentical transplantation can decrease the risk of cellular mediated graft rejection,[152] the adaptive immune response caused by recipient preformed alloantibodies caused by recipient's B cells cannot be easily mitigated by the escalation of chemotherapy intensity or post-transplant immunosuppression because of persistence of such antibodies in recipient's serum and/or tissues.

Although many anti-HLA antibodies can be detected in alloimmunized hematopoietic stem cell transplant recipients, only antibodies against donor HLA antigens (DSA) have been shown to be associated with transplant outcomes, and have become an important cause of graft rejection in HLA mismatched hematopoietic stem cell transplantation during the past decade.[48,49,52,195,200,201] This form of graft rejection is particularly important and more common in haploidentical transplants than in other types of HLA mismatched transplants due to the allosensitization of the female recipient through pregnancy against non-shared HLA antigens in a child donor.[48,49]

Anassetti and colleagues analyzed graft outcome of patients receiving allogeneic stem cell transplant from an HLA matched and mismatched relative donor and found that a positive crossmatch for anti-donor lymphocytotoxic antibody was an independent risk factor for engraftment failure, raising concerns about the role of HLA antibodies in graft rejection in allogeneic hematopoietic stem cell transplants with HLA mismatched donors.[52] Whether anti-HLA antibodies are causing engraftment failure has remained a matter of debate; however, several preclinical studies have showed that preformed anti-HLA antibodies present at the time of marrow infusion in multiply transfused mice, rather than primed T cells, are a major barrier against marrow engraftment.[202] Moreover, antibody-mediated rejection was extremely rapid in primed mice, and a higher bone marrow cell dose could partly overcome the predisposition to graft failure in sensitized mice,[202] presumably a higher antigen load would block more effectively circulating antibodies and allow engraftment. With evolving technology in recent years, novel solid phase immunoassays (SPI) that utilize purified preparations of molecules corresponding to single HLA antigens allow accurate identification of

HLA-antibody specificities.[203] Using modern technology of antibody detection, Ciurea et al. have demonstrated initially in haploidentical transplant recipients the clear association between DSAs and primary graft failure in recipients of T-cell depleted haploidentical stem cell transplantation with mega-doses of CD34+ stem cells. In this study, all patients with DSA were multiparous females and the most common reactivity was detected against HLA-DR and class I HLA antigens.[48] However, primary graft failure related to the development of antibodies against donor low expression HLA loci such as HLA-DPB1 and HLA-DQB1 has also been reported.[201] The significance of DSA in influencing the risk of graft failure has been confirmed in several subsequent studies using different platforms of haploidentical transplantation,[195,200] as well as in hematopoietic stem cell transplants with other mismatched grafts.[201,204,205] DSA have been shown not only to have a negative impact on engraftment but also have been shown to be associated with delayed engraftment, primary poor graft function,[200] and lower survival of haploidentical transplant recipients with DSA.[201]

The identification and specification of anti-HLA antibodies in transplant recipients can be performed using either cell-based crossmatch assays or SPIs. In cell-based crossmatch assays such as CDC or flow cytometry crossmatch test, donor T or B leukocytes are incubated with recipient serum to assess antibody reactivity with the donor's cell surface antigens via both complement dependent and non-complement dependent pathways. Even though it has been reported that the positive crossmatch test is strongly associated with the occurrence of primary graft failure,[52] this method has low sensitivity and specificity due to the possibility of detecting non-HLA antibodies, which might not be clinically relevant. Moreover, the cell-based crossmatch assays cannot identify antibody specificities in patients with complex antibody profiles.

In SPIs, the patient's serum is incubated with soluble HLA antigens bound to a solid matrix either by a microtiter plate (enzyme-linked immunosorbent assay; ELISA) or polystyrene beads (multiplexed multianalyte bead arrays) performed on a conventional flow cytometer or a fluoroanalyzer (Luminex). These tests are more sensitive than the conventional cell-based crossmatch assays and can be used for both antibody identification and semi-quantitively assess strength of HLA alloantigen-specific antibodies. Nonetheless, the assessment of DSA level using SPIs has not been well inter-laboratory standardized. Although cutoff values have been evaluated for different types of transplants, it is increasingly clear that there is a progressive increase in risk of rejection (in the absence of any treatment) with higher DSA levels, and, in TCR haploidentical transplants a higher risk was appreciated for patients with DSA > 10,000 MFI.[200]

Even though the exact mechanism by which DSA cause graft rejection in hematopoietic stem cell transplantation remains unclear, ample evidence in solid organ transplants has pointed toward complement-mediated cytotoxicity,[206–209] which has led to the assessment of functionality and ability of anti-HLA antibodies in complement fixation such as C4d and C1q assays. In haploidentical stem cell transplantation, our group has shown an association between high level of DSA (>5000 MFI) and their ability to activate complement pathway assessed by C1q test, and showed that patients who remained C1q positive at time of transplant experienced engraftment failure, while those who became C1q negative pre-transplant engrafted the donor cells.[49] Results from this study have prompted the EBMT recommendations on pre-transplant DSA and C1q assessment in all haploidentical transplant recipients when possible.[50] A follow-up study in patients who received treatment for DSAs confirmed these findings.[210]

Selecting a donor without the corresponding HLA antigens is the ideal option for recipients with DSA; however, when it is not possible pre-transplant desensitization treatment to decrease DSA levels and ensure a successful engraftment is required. To date several desensitization approaches have been studied, mostly in small numbers of patients with different graft outcomes. Most of these are based on a combination of different methods of immunosuppression, antibody removal, neutralization as well as antibody absorption.[49,195,211–215]

The investigators from MD Anderson Cancer Center (MDACC) initially reported outcomes of 12 haploidentical transplant patients with DSA receiving multimodality DSA desensitization with 3 sessions of alternate day plasma exchange with 1 to 1.5 × plasma volume (replaced with either fresh frozen plasma or 4% to 5% human plasma albumin), starting 1 week prior to admission for transplantation, followed by a single dose of rituximab 375 mg/m^2 the next day after completion of plasma exchange, and one day later by one dose of IvIg 1 g/kg. In addition, 5 patients received a buffy coat infused on day −1, prepared from 1 unit of blood from the same haploidentical donor to neutralize the remaining DSA prior to administration of hematopoietic stem cells. Even though the significant change of DSA level was not immediately observed, all patients who became C1q negative after treatment/before transplant successfully engrafted with the donor cells, suggesting that C1q negativity should be the primary goal of treatment rather than clearing of the non-complement binding DSA.[49] This protocol was later adopted by other institutions. In the updated report of 37 haploidentical recipients with DSA treated with this regimen at MDACC and City of Hope National Medical Center, reduction of DSA levels was observed after treatment and graft outcome and post-transplant survival of patients with initial DSA < 20,000 MFI and those with negative C1q after desensitization were comparable with control patients without DSA. In multivariable analysis, patients with initial DSA > 20,000 MFI and with persistent C1q+ after desensitization had a significantly lower engraftment rate, resulting in a significantly higher non-relapse mortality and worse overall survival than control group of patients without DSA.[210]

Treatment of Patients With Graft Failure After Transplantation

One of the main goals of transplantation is to prevent engraftment failure, which is associated with very high NRM and exposes patients to relapse due to lack of a functioning graft. As mentioned above, there are two main causes of engraftment failure—T-cell-mediated rejection and humoral rejection caused by DSAs. Knowing the cause of graft failure will help guide the treatment, which will need to include a second transplant performed as soon as possible after day 28 to avoid prolonged neutropenia and high mortality associated with this event.[216]

Only a few studies have explored salvage transplants after engraftment failure after transplantation.[217–219] In a recent study, Kongtim et al. showed that an urgent second transplant with a haploidentical donor and non-myeloablative conditioning (using the flurabine, cyclophosphamide and 2 Gray TBI regimen [Flu/Cy/TBI]) was associated with better long-term survival compared with any other salvage approach, and that changing the haploidentical donor to a donor with a different mismatched haplotype hopefully without DSA for those who received a prior haplo transplant was associated with better results. In addition, patients with AML/MDS and those who had a lower HCT-CI did better after salvage transplantation. Patients with AML/MDS who received an urgent haploidentical transplant from a different mismatched haplotype and with Flu/Cy/TBI conditioning had 3-year OS of 64.3%.[216]

In conclusion, growing evidence in the past decade has supported the significant role of DSA in mediating engraftment failure in haploidentical stem cell transplantation. Although several desensitization approaches have been explored, the number of patients treated is very small and it is unclear how effective these regimens are in reducing the risk of graft failure especially in patients with high DSA levels. The best available data is on the desensitization protocol developed at MDACC, described above. Until the more effective desensitization treatments are developed, this approach should be considered standard of care for patients with DSA levels up to 20,000 MFI. Patients with DSA should undergo desensitization treatment over 1 week with repeat DSA and C1q levels after 3 to 4 weeks and, if DSA remain greater than 10,000 or and/or C1q positive, transplantation should be discouraged. If levels decrease less than 10,000 MFI and C1q becomes negative, another course of treatment over 1 week followed by admission for transplant is recommended. If engraftment failure occurs an urgent rescue transplant with a haploidentical donor and non-myeloablative conditioning should be considered.

Toxicity From Chemotherapy

Complications Related to High-Dose Post-Transplant Cyclophosphamide

Hemorrhagic cystitis occurs in approximately a third of haploSCT patients receiving PTCy-based GVHD prophylaxis, is generally of limited severity, and most often attributed to polyomavirus (BK virus) infection.[220–223] Most patients tolerate very well PTCy, yet hemorrhagic cystitis can occur a few days following cyclophosphamide administration and is usually successfully prevented by adequate hydration and use of mesna during its administration.[224] As compared with hemorrhagic cystitis occurring within days after transplant, which is usually related to cyclophosphamide administration, cystitis that occurs a few weeks to a few months after transplant is usually related to BK virus reactivation (see Delayed Immunologic Reconstitution and Infectious Complications).

Another potential complication with the use of PTCy is development of cardiomyopathy (CMP), usually transient, which occurs in approximately 20% of patients, usually within the first month post-transplant. A retrospective analysis of 176 patients treated at a single institution found that impaired pre-transplant heart function did not influence the development of post-transplant CMP, rather other factors were more likely to be associated with development of CMP post-transplant, such as older age (>60) and a higher HCT-CI score ≥4.[225] Although in a case matched analysis, PTCy did not appear to be significantly associated with the development of CMP (21.9% vs. 14.8%, $P = .33$), a higher NRM and worse survival were observed in those who developed CMP post-transplant.[225,226] In addition to chemotherapy, excessive administration of IV fluids during chemotherapy may contribute to transient worsening in heart function and negatively impact transplant outcomes in these patients.[227,228]

Cytokine Release Syndrome

CRS is a syndrome characterized by the release of proinflammatory cytokines by the activated T cells, initially described as a complication of CAR-T-cell therapy. It manifests as fever (almost always present), which can progress to hypotension, hypoxia, and multiorgan failure.[228] A similar syndrome has been described in patients receiving haploidentical transplants.[229–231] CRS occurs typically within the first few days posttransplant, particularly when a peripheral blood stem cell graft is used. Patients develop high fever usually 24 to 48 hours after infusion of the graft, with negative blood cultures, which resolves after the first or more frequently after the second dose of cyclophosphamide administration. In several studies, approximately 90% of recipients of haploidentical transplants develop CRS,[230,231,233] usually mild (grade I–II). However, 12% to 17% can develop severe (grade III–V) CRS, which has been associated, in about half the patients, with multi-organ toxicity, higher NRM, and worse survival.[230,231,233] In the largest retrospective multicenter study to date, 451 patients receiving haploSCT were evaluated and authors found that severe CRS was significantly higher with peripheral blood versus bone marrow grafts (19% vs. 4.9%), and was associated with significantly higher NRM and worse survival.[233] In another study of 146 haploidentical transplant patients receiving PBSC grafts the cumulative incidence of NRM at 6 months for patients with severe CRS was 38% versus 8% for those who did not develop severe CRS.[231] Some reports suggested that patients with severe CRS may have delay in engraftment[230] and are more likely to develop acute GVHD post-transplant,[232] while others showed that mild CRS may be associated with a lower relapse and better survival post-transplant.[233]

Similar to CRS occurring in the setting of CAR-T-cell therapy, patients developing CRS after haploidentical transplantation were found to have higher IL-6 levels, and treatment with tocilizumab appears to be very effective for these patients.[230]

Delayed Immunologic Reconstitution and Infectious Complications

Rapid reconstitution of innate and adaptive immunity is critical for resistance to opportunistic infections after allogeneic SCT. Patients who undergo HLA-haploidentical SCT have had significantly impaired immune reconstitution as measured by delayed recovery of $CD4^+$ T cells compared with recipients of HLA-matched sibling grafts.[234] Similar findings have been reported in a pediatric group of patients.[235] This group showed that early reconstitution of $CD4^+$ T cells was associated with lower NRM and better overall survival. A number of factors contribute to impaired immune reconstitution after HLA-haploidentical SCT. Damage to lymphoid tissues resulting from conditioning may interfere with T-cell homing and the generation of immunologic memory. The rigorous TCD necessary to prevent GVHD in the haploidentical setting results in profound post-transplant immunodeficiency.[236,237] Finally, acute and chronic GVHD interfere with immune reconstitution,[238] in part through inhibition of thymopoiesis.[239] The delayed immune reconstitution after T-cell–depleted haploidentical SCT resulted in increased incidence of morbidity and NRM secondary to opportunistic infections. TCD haploidentical transplantation has been associated with delay in absolute lymphocyte count recovery[240] and a higher incidence of infectious complications compared with unmanipulated graft and PTCy-based GVHD prophylaxis.[19] We have also found that graft composition was independently associated with transplant outcomes. A balanced $CD4^+/CD8^+$ ratio (close to 1) was the most important determinant of transplant outcomes in haploidentical bone marrow transplantation; a low $CD4^+/CD8^+$ ratio (<0.85) and low $CD19^+$ numbers in the graft have been associated with higher NRM almost exclusively related to infectious complications,[7] findings that align prior reports which found a low $CD4^+$ count in the peripheral blood early post-transplant to be associated with higher NRM and worse survival.

Infectious Complications After Haploidentical Stem Cell Transplantation

Viral reactivation is common after haploidentical stem cell transplantation and occurs in approximately 70% of the patients by day 100 post-transplant.[221] Although less frequently encountered in haploidentical transplantation with PTCy-based GVHD prophylaxis,[19] viral reactivation remains a common complication, especially for CMV, HHV6, and BK virus (BKV), with very low incidence of EBV and adenovirus in adults.[221,241]

CMV reactivation occurs in 42% to 70% of patients receiving a haploidentical transplant with PTCy[220,221,241,242] after a median of approximately 40 days post-transplant. Although believed to be related mostly to haploidentical grafts, in a recent study performed by CIBMTR which compared incidence of CMV reactivation in three cohorts of patients: MSD with conventional GVHD prophylaxis ($n = 1605$), MSD with PTCy-based GVHD prophylaxis ($n = 403$), and haploidentical transplants with PTCy-based GVHD prophylaxis ($n = 757$) - it was found that the use of PTCy rather than a haploidentical donor was mainly responsible for a higher incidence of CMV reactivation (23%, 37%, and 42%, respectively; $P < .001$).[243] A major recent advance in prevention of CMV reactivation and development of CMV disease has been the use of letermovir in the first 100 days post-transplant,[244] which has also been shown to decrease significantly the incidence of CMV reactivation in haploidentical transplant patients receiving PTCy-based GVHD prophylaxis (68.8% to 21.9%, $P < .001$).[245]

BK virus hemorrhagic cystitis is seen with increased frequency in alternative donor transplants (MUD, cord blood, and haploidentical transplants)[246–248] and is more common in younger individuals[246] and patients receiving myeloablative conditioning.[222,247,249]

Although the great majority of patients receiving a haploidentical transplant with PTCy may have asymptomatic BK viruria (80% to 90%) only approximately half will develop symptomatic cystitis, mostly between 1 and 2 months post-transplant (median 38 days). The incidence of BKV cystitis appears to vary based on intensity and type of conditioning, with lowest incidence with NMA conditioning (23%),[220] 30% to 40% with melphalan-based conditioning and TBI-based conditioning,[241] and up to 75% with busulfan-based conditioning.[242] Other factors associated with BKV cystitis were CMV reactivation, development of GVHD, and/or treatment with steroids.[222,249] In a study from MDACC, significant (grade II–IV) BKV cystitis occurred in 24% of the patients receiving melphalan-based conditioning, while 8% experienced severe cystitis requiring bladder irrigation or nephrostomy tube placement.[241,250] Although development of BKV cystitis has been associated with increased morbidity and prolonged hospitalization, no impact on survival has been observed in several studies as 90% of the cases resolve after 4 to 6 weeks.[222,241,249] Treatment of BKV hemorrhagic cystitis remains mostly symptomatic with adequate hydration to prevent significant clot formation and ureteral obstruction, bladder irrigation, and pain control, as no effective drug treatment exists. However, recent success has been seen with viral CTLs, either targeting only BKV or more commonly with multi-virus CTLs with resolution of symptoms within 4 weeks of treatment in most patients.[251,252]

Relapse Post-Transplant

Mechanisms of Disease Relapse Post Haplo-Transplant

As treatment-related mortality has progressively improved post-transplant,[253] relapse has emerged as the most common cause of treatment failure, including after HLA-haploidentical SCT. There is substantial controversy regarding whether HLA disparity between donor and recipient reduces relapse through a more intense GVH reaction. Most studies have not shown decreased relapse rates after HLA-haploidentical as compared with HLA-matched SCT,[177,187,254] although such studies may be confounded by significant differences between donor types in the GVHD prophylaxis regimens employed. Other studies have shown a decreased risk of relapse associated with HLA mismatching,[255] especially for patients with poor-risk hematologic malignancies.[8] More recent data suggests that it is not the number of mismatched HLA loci associated with lower relapse rate but rather a higher number of molecular mismatches quantified by mismatched eplet load at each HLA locus.[35]

Approximately one-third of leukemic relapses after TCD HLA-haploidentical SCT are associated with loss of the mismatched HLA locus due to acquired uniparental disomy, a process in which the unshared HLA haplotype on chromosome 6 is replaced by the shared HLA haplotype.[256,257] HLA-alloreactive T cells may be providing the selective immunological pressure that results in the emergence of these variants, because relapse is never associated with loss of the shared HLA haplotype, and HLA loss by uniparental disomy suggesting that this could be a mechanism specific to haploSCT. However, recent data found this mechanism of relapse in transplants with all donor types and seem to correlate with the number of HLA mismatches.[258] In addition, there is growing evidence of another immune escape mechanism as cause of relapse after allogeneic transplantation, in general, with downregulation of HLA class II molecules or upregulation of inhibitory molecules by the tumor cells.[259–261] Clinically, relapses of AML associated with loss of mismatched HLA tend to occur later than relapses with preserved HLA expression (307 days vs. 88 days; $P < .001$),[262] suggesting that they originate in a smaller clone, resistant to the immunologic effect of the graft,[258] and tend to carry a similarly poor prognosis (OS at 6 months after relapse was 28.5% for patients with HLA loss and 27.4% for patients with "classic" relapse). These considerations may have important therapeutic implications as donor lymphocyte infusion (DLI) may not be effective in light of the loss of the major targets of alloreactive T cells, while upregulation of inhibitory molecules may potentially respond to checkpoint inhibition.[258] Survival may be improved by performing a second transplant for patients with HLA loss, especially from a donor with a different mismatched haplotype.[263]

Treatment of Relapsed Hematologic Malignancy After Human Leukocyte Antigen-Haploidentical Stem Cell Transplants

Unmanipulated DLIs have been administered to patients with relapsed hematologic malignancy after HLA-haploidentical SCT with PTCy. In one study, DLI was administered as a series of escalating infusions (ranging from 10^3 to 10^7 T cells/kg), with or without preceding chemotherapy, to patients with acute leukemia, in molecular ($n = 20$) or hematologic ($n = 12$) relapse, or to patients with Hodgkin lymphoma ($n = 10$).[264] The incidence of acute GVHD after haploidentical DLI in these groups was 15%, 17%, and 10%, respectively, and the response rates were 45%, 33%, and 70%. Two-year actuarial survival rates were 43%, 19%, and 80%, respectively. In a second report, 40 patients, including 16 with AML and 11 with lymphoma, received DLI starting at a dose of 10^5 $CD3^+$ T cells/kg with subsequent dose escalation.[265] The most commonly used first dose was 10^6 $CD3^+$ T cells/kg. Acute GVHD developed in 10 patients, 6 patients had grades III–IV, and 3 developed chronic GVHD. Twelve patients (30%) achieved a complete response with a median duration of 11.8 months. Eight patients were alive in complete response at the time of reporting, six for more than 1 year.[265]

The Beijing group developed a modified DLI approach in which patients with relapsed leukemia after haploSCT received chemotherapy and peripheral blood leukocytes from filgrastim-treated donors followed by an immunosuppressive drug (CsA or methotrexate) for 2 to 8 weeks after DLI.[266] One hundred twenty-four patients in relapse after haploSCT received chemotherapy followed by the modified DLI containing a median of 4×10^7 $CD3^+$ T cells/kg of recipient weight. The cumulative incidence of DLI-associated acute GVHD was 53.2% for grades II–IV and 28.4% for grades III–IV. The duration of GVHD prophylaxis after DLI was the only risk factor for DLI-associated grades III–IV acute GVHD ($P < .05$). The 2-year OS, NRM, and cumulative incidence of relapse after DLI were 47.2%, 34.1%, and 34.6%, respectively. A subsequent study compared the antileukemic effects of chemotherapy alone ($n = 32$) versus chemotherapy followed by modified DLI ($n = 50$), with immunosuppression given for 4 to 8 weeks after DLI, in patients with relapsed acute leukemia after haploSCT.[265] In patients receiving chemotherapy followed by modified DLI, the CR rate was significantly higher (64.0% vs. 12.5%; $P = .000$), the incidence of relapse was significantly lower (50.0% vs. 100.0%; $P = .000$), and DFS was significantly improved (36.0% vs. 0.0%; $P = .000$) compared with patients receiving chemotherapy alone. Multivariate analysis demonstrated that patients with chronic GVHD after intervention ($P = .000$) and patients receiving chemotherapy followed by modified DLI ($P = .037$) had a lower relapse rate.

In summary, hematologic malignancies in relapse after HLA-haploidentical SCT can be treated with chemotherapy + DLI with the goal to achieve remission. Patients with relapse of acute leukemia within the first 6 months after transplant generally have a poor prognosis. Only a minority of patients will achieve remission to salvage therapy ± DLI and, if they do, are younger, greater than 6 months from the first transplant, no infection, good performance status, and low comorbidity index and are taken urgently to a second transplant, preferably with a donor with a different mismatched haplotype and conditioning regimen.[263] For patients with relapse of leukemia after 6 months, HLA typing of the leukemic blasts is recommended. If mismatched HLA expression is preserved, chemotherapy ± DLI may be used. For patients in overt hematologic relapse treated with PTCy-based GVHD prophylaxis, a starting dose of 10^6 $CD3^+$ T cells/kg is usually recommended. If mismatched HLA alleles have been lost, salvage chemotherapy followed by an urgent second transplant procedure from a different donor may provide the best outcome.[263,268]

Prevention of Relapse After Haploidentical Stem Cell Transplantation

Outcomes of patients with disease relapse after transplant are very poor, with only approximately 20% of patients responding to salvage treatment, and only approximately 20% of these patients will achieve disease control and meet transplant eligibility, and are able to proceed to a second transplant. Hence preventing post-transplant relapse, especially in patients with high-risk leukemia, becomes of paramount importance to improve survival after allogeneic transplantation.

Several cell-based approaches have been used to prevent disease relapse post-transplant (Table 107.3), initially with unmodified DLI, more recently with genetically modified T cells and ex vivo expanded NK cells. These reports suggest that cellular therapy with lymphocytes obtained from the same haploidentical donor can be safely and successfully applied post-transplant with encouraging results.[267]

Unmodified Donor Lymphocyte Infusion

One of the major advantages of using haploidentical donors for transplantation is the opportunity to collect donor T cells or NK cells to treat or prevent relapse post-transplant. This approach has been used primarily in patients with persistent MRD or with decrease in chimerism after transplant.[270–275] Although there is concern with increase in the potential to induce severe aGVHD after haploidentical DLI, the incidence of GVHD was not shown, in general, to be higher than in HLA matched transplants,[264,265,276] possibly in part due to the tolerizing effect of PTCy. In one of the earliest reports, 40 patients with hematological malignancies received an unmodified haploidentical DLI for relapsed disease after haploSCT with PTCy-based GVHD prophylaxis).[265] Most patients received 1×10^6/kg CD3$^+$ T cells. Acute GVHD developed in 25% of patients, and 15% of patients had grade III–IV aGVHD. Efficacy of DLI appears to be improved with the use of cytoreductive therapy prior to the DLI infusion, with higher likelihood of achieving CR and improved survival in some studies.[264,276] DLI is expected to be more effective in patients with low tumor burden, such as patients with minimal residual disease,[277] in patients with lymphoid malignancies,[264,278] and when administered in conjunction with cytoreductive chemotherapy.[265,272]

Modified Donor Lymphocyte Infusion With a Safety Switch

The most important risk of administering donor lymphocytes early post-transplant is the development of severe acute GVHD, which could be potentially controlled by inserting a suicide gene in the donor T cells. If significant aGVHD develops, T cells can be turned off by activating this switch with a drug to avoid excessive aGVHD. This approach has so far been investigated to boost post-transplant immune recovery after T-cell-depleted haploidentical grafts. Ciceri et al. infused DLI engineered T cells to express herpes simplex virus-thymidine kinase suicide gene that can be targeted by ganciclovir to induce apoptosis.[83] Grade I–IV aGVHD developed in 20% of the patients and GVHD was successfully controlled by inducing the suicide gene with ganciclovir. However, ganciclovir is commonly used post-transplant to control CMV reactivation or disease thus may not be the ideal drug in this setting. Another approach developed by the Baylor group used engineered DLI to express an inducible caspase-9 transgene.[84] This gene can be induced by an inert dimerizing drug leading to rapid cell death. In an initial report, GVHD which occurred in 4 of the 5 haploSCT patients after infusing the safety switch-modified T cells, was rapidly stopped by administration of the dimerizing drug.[84] Long-term outcomes were reported for 10 haploSCT pediatric patients infused with the same product, showing persistence of these modified cells for over 2 years and potentially contributing to control of opportunistic infections post-transplant and promoting endogenous T-cell recovery.[85] This approach has been explored after TCD haploidentical transplantation with encouraging results in pediatric patients with acute leukemia.[279]

TABLE 107.3 **Post-Transplant Cellular Therapies to Prevent Relapse After Haploidentical Transplantation (Selected Studies)**

Approach	Advantages	Limitations	References
Unmodified DLI	Increase graft-versus-tumor effect	Not targeted to specific antigen(s) Potential for development of severe GVHD especially with higher doses Efficacy possibly higher with chemotherapy	265,274,276,297
Modified DLI with a "safety switch"	Increase graft-versus-tumor effect "Safety switch" allows elimination of T cells in case of GVHD development	Not targeted to specific antigen(s) Clinical efficacy not yet demonstrated in large number of patients	83,84,298
Chimeric antigen receptor modified T cells (CAR-T)	Genetically modified T cells to express a CAR (e.g., CD19) Could provide graft-versus-tumor effect Low risk of GVHD	A small number of patients treated to date Efficacy unproven	284,299
Ex vivo expanded NK cells	Potential graft-versus-leukemia effect without GVHD	Clinical efficacy demonstrated in a phase II study	68,289
Photodepleted T cells	Depletion of alloreactive T cells by photodepletion	Efficacy in phase II study Randomized phase III study stopped early	300,301
δγ DLI	Selected δγ T cells Potential to increase anti-tumor effect especially after αββTCD haploSCT ? Limited/no GVHD potential	Efficacy unproven	302

DLI, Donor lymphocyte infusion; *GVHD*, graft-versus-host disease; *NK*, natural killer; *TCD*, T-cell depleted.

Chimeric Antigen Receptor Modified T Cells

While DLI offers a non-specific anti-tumor activity, its effect does not target directly the malignant cells. The recent success of CAR-T-cell therapy in patients with CD19 B-cell lymphoid malignancies[280–282] prompted investigation of this form of therapy for patients with advanced B-cell ALL after transplant to improve relapse rate.[283,284] Several studies reported experience with donor-derived CAR-T-cell therapy administered for relapsed disease after allogeneic stem cell transplantation.[283,285,286] Kochenderfer and colleagues used donor-derived allogeneic CAR-T cells for patients with B-cell lymphoid malignancies relapsed after allogeneic stem cell transplant without lymphodepleting chemotherapy and obtained response in 30% of the patients.[283] The MDACC group explored the use of CAR-T cells administered in the peri-transplant setting to prevent disease relapse for patients with B-cell lymphoid malignancies and improve outcomes after autologous and allogeneic transplantation. Results from the phase I clinical trial for patients with B-cell ALL receiving allogeneic transplant showed safety of this approach and very low relapse rate. Eight patients received a haploSCT followed by donor-derived CAR-T-cell infusion with 1-year PFS and OS of 75% and 100%, respectively, and with no increased risk of GVHD.[282] These preliminary studies suggested that allogeneic CAR-T cells can be safely administered post-transplant to treat or prevent disease relapse without significant GVHD.

Infusion of Ex Vivo Expanded Natural Killer Cells

NK cells are part of the innate immune system capable of recognizing and killing malignant or virally infected cells. NK cells recognize and target "foreign" cells that lack one or more HLA class I alleles specific to the inhibitory receptors (killer immunoglobulin-like receptors-KIRs) or by increasing activator signals on malignant cells.[287] High NK cell numbers early post-transplant,[288] as well as high NK cell numbers in the haploidentical bone marrow graft,[7] have been associated with lower incidence of GVHD. Although prior studies in T-cell depleted haploidentical transplants showed lower incidence of relapse when patients had a KIR-ligand mismatched (KIR-LM) donor,[70] several studies in T-cell-replete (TCR) haploSCT (both ATG-based or PTCy-based) suggest no role of KIR-LM in lowering relapse risk, at least after TCR haploidentical transplantation.[76] Although there is no convincing role of KIR-LM in decreasing relapse post-transplant, our group explored the anti-tumor effects of NK cells in the post-transplant setting and hypothesized that high doses of ex vivo expanded NK cells would decrease the relapse rate after transplant with very encouraging results. In a phase I dose-escalation study, using mb-IL21 expanded NK cells, 13 patients with high-risk myeloid malignancies received escalating doses of donor-derived NK cells on days −2, +7, and +28 of haploSCT.[68] The study demonstrated feasibility of infusing high doses of ex vivo expanded NK cells after transplant without toxicities or GVHD. A remarkable low post-transplant relapse was observed.[68] Preliminary results from the phase II study confirmed these findings, and, in an independent matched-pair analysis performed by CIBMTR, NK-cell-treated patients showed a significantly lower 2-year relapse rate of 4% vs. 38% ($P = .014$) and improved PFS (66% vs. 44%) ($P = .1$) compared with patients who did not receive NK cells.[289] Based on these promising results, phase II and a phase III randomized study with and without NK-cell administration early post-transplant are planned.

DONOR SELECTION FOR HAPLOIDENTICAL TRANSPLANTATION (TABLE 107.4)

The great majority of patients have more than one potential haploidentical donor available for donation and include first-degree relatives (parents, children, siblings, half-siblings) and second-degree relatives (cousins, nieces, nephews, and grandchildren). Several patient and donor characteristics have been shown to influence the choice of donor, including medical and psychologic suitability of the donor, donor age, sex, the presence of DSA in the recipient's serum, degree of donor-recipient HLA mismatch, red blood cell ABO group compatibility, and donor and recipient CMV serology. Regardless of transplant platform, there are two absolute contraindications to donation: (1) the donor is medically or psychologically unfit to donate or (2) the recipient has high levels of DSA against donor HLA antigens (>20,000 MFI or C1q remains positive after desensitization therapy)[210] (see also Graft Failure).

TABLE 107.4 Algorithm for Donor Selection in Haploidentical Stem Cell Transplantation With Post-Transplant Cyclophosphamide

Priority	TCR Haploidentical SCT
1	No DSA against donor[a]
2	Younger preferred to older donor
3	Male donor for male recipient[b]
4	Sibling or offspring over parent donor
5	Between parents, father is preferred over mother
6	ABO matched preferred to minor ABO mismatch to major ABO mismatch
7	First-degree relative preferred over second-degree relative[c]
8	KIR ligand match preferred to KIR ligand mismatch[c]
9	NIMA mismatch preferred over NIPA mismatch[c]

[a] If a donor without DSA is not identified desensitization treatment may be performed for patients with DSA up to 20,000 MFI (MDACC desensitization protocol only).
[b] Avoid older female donors.
[c] Data available at present only for the GIAC protocol.
KIR, Killer immunoglobulin ligand; *NIMA*, non-inherited maternal antigens; *NIPA*, non-inherited paternal antigens; *TCR*, T-cell–replete.
Adapted from Ciurea SO, Al Malki MM, Kongtim P, et al. The European Society for Blood and Marrow Transplantation (EBMT) consensus recommendations for donor selection in haploidentical hematopoietic cell transplantation. *Bone Marrow Transplant*. 2020;55(1):12–24.

First, it is important to mention that the transplant platform (i.e., T-cell-depleted versus T-cell-replete haploidentical transplantation) may influence donor choice. For example, in a study of 118 patients receiving mega-dose TCD transplants, 5-year event-free survival was better in patients who received transplants from the mother than from the father (50.6% ± 7.6% vs. 11.1% ± 4.2%; $P < .001$), with better survival resulting from both a reduced incidence of relapse and transplant-related mortality. The 5-year event-free survival was 27.0% ± 6% and 25.5% ± 9% for patients who received transplants from an HLA haploidentical sister ($n = 30$) or brother ($n = 49$), respectively ($P = .63$). On the basis of these results, the authors suggested that the mother of the patient is the preferred HLA-haploidentical donor for TCD haploSCT. The opposite is true for TCR haploidentical transplants where older female donors have been found to be associated with higher incidence of severe acute GVHD, higher NRM, and worse survival.[7,76] Incidence of severe grade III–IV aGVHD was found to be as high as 54% in older female donors owing to a higher CD4/CD8 ratio in the bone marrow graft of these donors, combined with lower % CD56 (NK cells), lower CC34+ (stem cells), and CD19+ (B-cells) in the graft found in older donors caused increased NRM in these patients.[7] Similar results were reported by Wang et al. who studied outcomes of 1210 patients treated with the GIAC protocol. With this platform, younger donors and male donors were found to be associated with less NRM and better survival. By contrast, use of maternal donors was associated with higher incidence of acute and chronic GVHD, and worse survival.[121] Similar results have been reported in haploSCT with PTCy.[290,291] Other important factors in selecting donors for haploidentical stem cell transplantation include children rather than siblings for older recipients,[290,291] ABO matched vs. minor ABO mismatch vs. major ABO mismatch,[292] first-degree versus second-degree haploidentical donor, KIR ligand match versus KIR ligand mismatch donor, and NIMA versus NIPA mismatch donor for TCR haploSCT patients treated with the GIAC protocol.[121] The use of second-degree family donors has been reported by the Johns Hopkins group to be feasible and associated with similar outcomes as use of first-degree haploidentical donors[293]; however, to date, no study has evaluated outcomes with second- versus first-degree haploidentical donors in patients receiving PTCy-based GVHD prophylaxis (Table 107.4). The last important issue is the role of NK-cell alloreactivity appreciated by the presence of KIR ligand mismatch (KIR-LM) between the donor and recipient in haploidentical transplant recipients receiving a TCR graft, previously shown to be associated with lower relapse and improved survival in patients receiving TCD haploSCT.[70] Recent data on a large number of patients receiving PTCy-based GVHD prophylaxis showed that patients with a KIR-LM had higher NRM and decreased survival compared with KIR ligand match recipients,[75] findings concordant with reported data by the Beijing group with the GIAC protocol.[121] Consequently, the use of a KIR-LM haploidentical donor cannot be recommended at the present time in patients receiving a TCR haploidentical transplantation.

CONCLUSIONS AND FUTURE DIRECTIONS

HLA-haploidentical donors are a rapid and near universally available source of stem cells for transplantation. Major HLA mismatch is associated with intense bidirectional reactions resulting in higher incidences of graft failure and GVHD, thus effective control of alloreactive reactions is needed in this setting. Due to higher NRM, haploidentical transplants have evolved from complete depletion of T cells from the graft to a partial T-cell depletion or infusion of full graft with effective GVHD prevention. Three modern approaches to haploSCT have emerged in the recent years: (1) High-dose post-transplant cyclophosphamide-based GVHD prophylaxis, (2) the GIAC protocol involving administration of ATG, filgrastim-mobilized marrow and PBSCs, and intensive posttransplant immunosuppression, and (3) alpha-beta T-cell depleted haploSCT. While multiple retrospective studies comparing outcomes with different donor sources have been performed, only one randomized study to date has been done comparing outcomes of haploidentical transplants with PTCy and cord blood transplants. Prospective randomized trials comparing different approaches to haploidentical transplantation as well as different donor sources with intent-to-treat will be needed to determine the donor priority for patients referred for allogeneic transplantation.

Priorities for future research include prevention of disease relapse, improvement of immunologic reconstitution post-transplant, as well as exploration of graft manipulation to improve outcomes after haploidentical stem cell transplantation.

CHAPTER 108

CORD BLOOD TRANSPLANTATION

Joseph E. Maakaron, Najla El-Jurdi, and Claudio G. Brunstein

CORD BLOOD AS A STEM CELL SOURCE

It is well established that ethnic minorities have a low likelihood of matching with an unrelated hematopoietic stem cell donor.[1] In recent years, there has been increasing interest in alternative stem cell donors given the genetic heterogeneity of our population coupled with diminishing family size. Cord blood (CB) represents an alternative donor type for hematopoietic cell transplantation (HCT) and yields outcomes similar to matched donors. In addition, CB has several unique characteristics. CB units are readily available for procurement from CB banks when urgent transplants are needed. Properties of the unit are also known ahead of time including any evidence of microbial contamination, total nucleated cell (TNC) dose, and in many instances, the CD34+ cell dose and viability. Given the immaturity of stem cells and accompanying T cells, the risks of acute and chronic graft-versus-host-disease are relatively low, requiring less stringent HLA (human leukocyte antigen) matching.[2] Cord blood transplantation (CBT) has also been associated with a decreased risk of relapse, especially in the setting of minimal residual disease.[3]

CORD BLOOD UNIT SELECTION

Just as optimal donor selection is key to the success of a stem cell transplant (SCT), a successful CBT depends on ideal unit selection. Experience in CB unit selection requires time and understanding of multiple variables that represent CB unit quality and affect outcomes. Both the American Society of Transplant and Cellular Therapy and the National Marrow Donor Program have resources to support graft selection (https://network.bethematchclinical.org/education/education-catalog/cord-blood-unit-selection/). Consultation with a transplant center experienced with CB transplantation may also be considered. There are several characteristics that are typically considered in the selection process, and transplant centers may have different CB unit selection algorithms where they may give priority to one CB characteristic over another, as recently outlined.[2] The main CB unit characteristics to be considered in graft selection are discussed in the following sections.

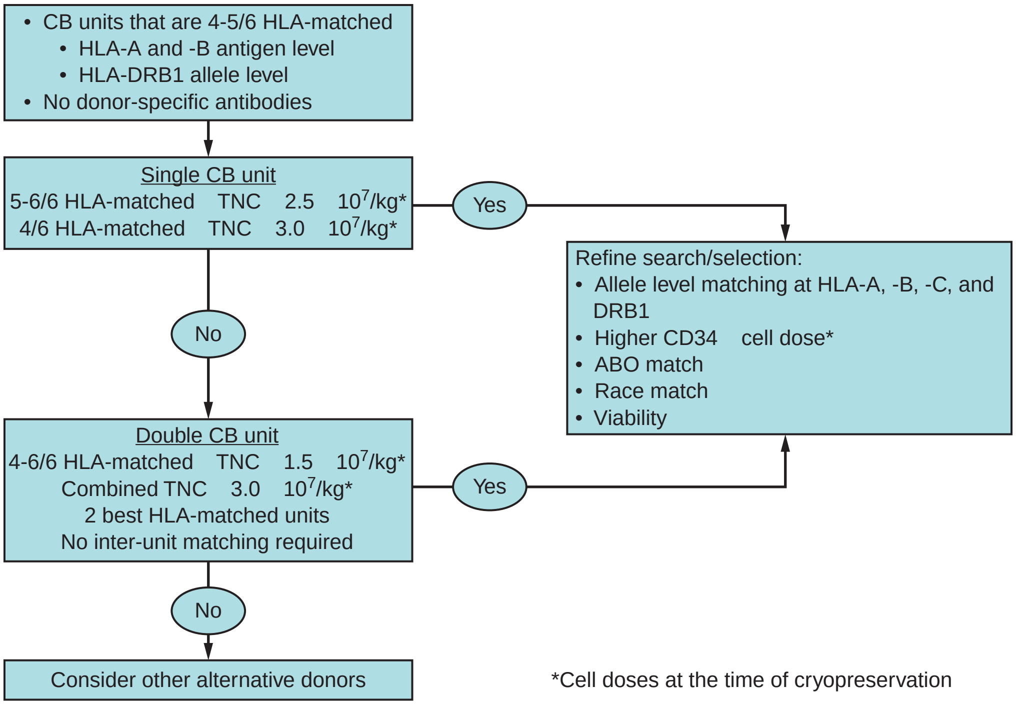
Cell Dose

One of the main determinants of transplant-related mortality (TRM) in CBT is the infused TNC and CD34+ cell doses as they correlate with incidence and time to hematopoietic recovery.[4] Historically, TNC was the only cell dose variable considered at the time of CB unit selection. The TNC dose is still relevant today, and most centers consider a TNC of 2.5 to 3.0 × 10^7/kg suitable as a single CB unit graft. However, the underlying diagnosis must be taken into consideration as those with nonmalignant disease require higher cell doses to achieve reproducible engraftment, estimated between 4 to 5 × 10^7/kg.[5–7] Cell doses below this threshold result in delayed hematopoietic recovery, higher risk of graft failure, and increased treatment-related mortality (TRM). The limited cell dose in each individual unit can be in part overcome by the utilization of double CB unit grafts, as outlined in the following sections. More recently, greater emphasis has been given to the importance of considering the CD34+ cell dose as a measure of CB unit quality and potency. A minimum pre-cryopreservation CD34+ cell dose of 0.9 to 1.1 × 10^7/kg is typically considered. Recently stored units will have both pre-cryopreservation TNC and CD34+ cell counts available for graft selection, especially with red cell depletion and modern banking procedures. While TNC and CD34+ cell counts were expected to be correlated, a recent study found that the correlation between TNC and CD34+ was in fact poor ($r = .024$).[8] The ratio of CD34+ to TNC was 0.34% with an interquartile range of 0.23% to 0.48%.[4,8] Note that when the TNC/CD34+ ratio is significantly outside this range, other unit characteristics, delivery conditions, and experience with the CB bank should be considered in unit selection. In summary, current recommendations are to take both the TNC and CD34+ cell counts into consideration in CB unit selection (Fig. 108.1).[2]

The use of CB for allogeneic HCT started in a pediatric setting, where younger and smaller patients may receive a TNC dose of 5 to 10 × 10^7/kg. In part due to TNC dose, CB grafts in children achieve consistent engraftment, with outcomes similar to unrelated adult donors.[9,10] As investigators attempted to extend CB to adult patients, it became evident that cell dose was a barrier to the efficacy of this donor type for larger and adult patients. Initially developed at the University of Minnesota as a platform to study novel graft manipulations, the use of two CB units as a graft (double CB graft) extended this donor type to a physically larger patient population.[11] Double CB transplantation rapidly became an approach commonly used to overcome the cell dose limitation of a single unit. While the principles of quality and HLA-matching apply to the selection of each unit composing the double CB graft, the most commonly used TNC cell dose threshold for each of the two units is a minimum of 1.5 × 10^7 TNC/kg. There is no widely defined CD34+ cell dose for each individual unit in double CB transplantation. Prospective randomized data in children[9] and retrospective registry-based data in adults[12,13] have shown that the outcomes of transplantation with single or double units result in similar outcomes once the pre-cryopreservation TNC threshold ≥2.5 × 10^7 TNC/kg is met. However, children are still more likely to find suitable single units than adults. Thus, the use of double CB graft is still important in extending this donor type to older and larger patients.

The growth of the inventory of CB over the years has allowed for more frequent identification of single unit grafts with the adequate cell dose for children and certain adult patient populations. Once these larger units become available in the national and international donor search platforms, they tend to be in the CB banks inventory for a short period of time. Moreover, to meet HLA-matching requirements, minorities continue to find only smaller units and require double CB drafts.[14] Current efforts in overcoming the cell dose limitation and making a larger proportion of the existing inventory available to more patients are focused on ex vivo expansion, as discussed later in this chapter.

While methods used to collect and cryopreserve a CB unit may impact its quality, conditions of storage and thaw of the CB unit may also have an impact on the final quality of the CB product. Thus, beyond using proper established and validated thaw methodology, it is necessary to monitor post-thaw cell counts as these counts also play a crucial part in optimizing outcomes. A recent report in the double CB setting described the effect of post-thaw cell count and viability on outcomes and found that a higher CD34+ cell dose and a CD34+ cell dose viability >75% resulted in a higher likelihood of engraftment and CB unit predominance.[15] While this study was in the



• CB units that are 4-5/6 HLA-matched
• HLA-A and -B antigen level
• HLA-DRB1 allele level
• No donor-specific antibodies
Single CB unit
5-6/6 HLA-matched TNC 2.5 10^7/kg*
4/6 HLA-matched TNC 3.0 10^7/kg*
Yes
Refine search/selection:

double CB transplant setting, these findings must also be considered in the context of single CB transplantation; if a single CB unit graft has poor TNC or CD34+ recovery and/or viability, close monitoring and early intervention for graft failure should be considered.

HLA-Matching

The HLA-matching of CB units to the patient historically required 4–6/6 matching at HLA-A and HLA-B at the antigen level and HLA-DRB1 at the allele level. Despite this low level of HLA-matching in most cases, the incidence of graft-versus-host disease (GVHD) with CBT has been relatively low compared to bone marrow (BM) transplants using other stem cell sources. There is growing consensus in the literature regarding the importance of better HLA-matching in CB transplantation. The data in single CB in children suggest that 6/6 allele level HLA-matched CB results in the best outcomes.[16] In contrast, in adult patients closer HLA-matching considering 6 to 10 loci does not seem to affect survival in either single or double CB settings.[17–19] However, in the double CB setting when the dominant unit is better HLA-matched to the recipient, it seems to lead to improved outcomes.[20] In the adult population, in particular in ethnic minorities, selected CB units tend to be more HLA-mismatched in order to meet minimum TNC criteria. A lower level of HLA-match may result in a lower risk of relapse, but this is offset by an increased risk of TRM, resulting in similar survival. The novel ex vivo expansion platforms have the potential to shift this balance by allowing the selection of initially smaller but better HLA-matched CB units that can then be expanded to suitable cell doses for most patients. When widely available, this type of innovation will make a larger proportion of the CB inventory available for transplantation of larger and adult patients. Currently, HLA-matching in CB graft selection still starts with the historical standards described. Once this initial search identifies numerous potential CB units, experienced CB transplant centers will further refine the selection by selecting units with the closest allele level HLA-matching considering HLA-A, -B, -C, and -DRB1. In the setting of double CB transplantation, the two units should be selected based on each individual unit's characteristics aiming for the best conventional and, if possible, allele HLA-matching to the recipient, with no need to match the units to each other.[21]

Cord Blood Bank

CB banks are a key element for successful CB transplantation. Under appropriate CB unit selection for banking, quality control, cryopreservation, and storage standards, CB units can be stored and available for treatment for many years. For example, the storage of CB units that have had their volume reduced to around 25 mL have better cell recovery as compared to those that have larger volumes.[15] It is also important that units are red cell depleted as units not depleted of red cells have been associated with a high risk of serious infusion reactions. The familiarity of the transplant center with the CB banks and their practices is another factor to be considered in CB graft selection. The CB bank community is self-regulated with most banks seeking accreditation by NetCord-Foundation for the Accreditation for Cellular Therapy (FACT), which has helped make CB Bank practice more consistent. Notably, CB banks that were NetCord-FACT accredited had higher and more consistent post-thaw cell viability in one study.[15] In addition, CB banks may also undergo licensure by the US Federal Drug Administration (FDA). CB units collected by licensed CB banks are labeled, licensed, and dispensed as a drug, whereas units collected prior to licensure or in unlicensed CB banks and labeled as unlicensed have to be dispensed and used for transplantation under an Investigational New Drug (IND) application. Engraftment and survival are similar whether using a licensed or unlicensed CB unit.[22] Please refer to papers on the topic of CB banking for a more complete discussion of this topic.

DONOR-SPECIFIC ANTIBODIES

The testing for donor-specific HLA-antibodies (DSA) is an important selection criterion in unrelated and mismatched HCT. The data in single CBT have consistently shown that the presence of DSA with mean fluorescence intensity (MFI) of 1000 is associated with a significantly higher incidence of graft failure that ranges from 20% to 68%.[23–26] The presence of HLA-antibodies, even if not directed against the graft, may be associated with a higher risk of graft failure.[23] This is further suggested by the presence of higher titer antibodies resulting in non-engraftment with either CB unit in double CB transplantation.[26] When comparing patients with DSA who were engrafted to those who had graft failure, the latter had a higher median MFI. There are also some data suggesting that DSA against HLA-C, DP, DQ, and DRB3/4/5 may result in a higher risk of graft failure.[25] The data in double CB transplantation were less clear in part because of the varying MFI thresholds used in different reports.[26–29] Nonetheless, owing to the strong impact seen in single CB transplantation, testing for DSA has also been incorporated in double CB graft selection by most centers. In summary, testing for DSAs against high expression HLA loci and using virtual cross-matching to assist with the selection of CB units is highly recommended. While HLA A-, B-, C-, -DQB1, and -DRB1 are typically available in current confirmatory typing reports, some cases may require additional HLA typing for determinating HLA-DP and -DRB3/4/5, adding time and complexity to the selection process. While most centers will use an MFI greater than 1000 as positive, higher-risk DSAs are those with MFI greater than 3000. Consultation with the immunology laboratory to determine the relevance of DSAs is also valuable. Administration of rituximab, intravenous immunoglobulin, and bortezomib with or without plasma exchange has been used immediately prior to conditioning to reduce the DSA titer and proceed with the transplant with a specific CB unit.[30,31] DSA debulking requires further evaluation before it can be widely applied in CB transplantation care, and selecting an alternative CB unit with no DSA may be the best course of action, if possible.

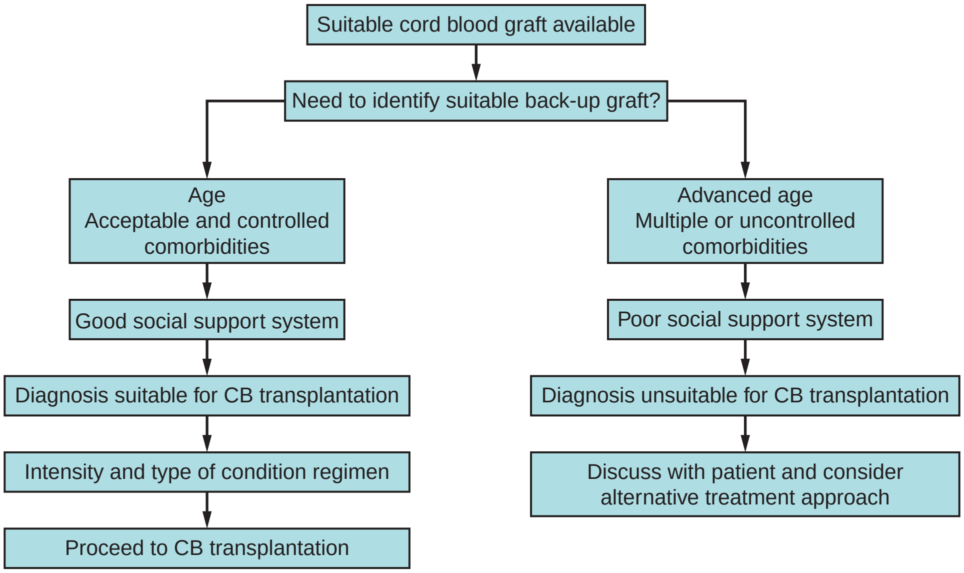
CONDITIONING REGIMENS IN CORD BLOOD TRANSPLANTATION

Initial CBT conditioning regimens were designed to provide additional immunosuppression to facilitate engraftment in the context of HLA-mismatching. Early regimens included anti-thymocyte globulin (ATG) and a short course of steroids, which resulted in successful engraftment in children but had limited success in adult patients.[32] The introduction of fludarabine (FLU) to the conditioning regimens

TABLE 108.1 **Selected Conditioning Regimens Used in Cord Blood Transplantation**

Reference	Center	Conditioning Regimen
Myeloablative Conditioning Regimens		
Barker et al. Blood 2005[11]	University of Minnesota, USA	• Cyclophosphamide 60 mg/kg/day days –7 and –6 • Fludarabine 25 mg/m^2/day days –8 to –6 • Total body irradiation 1320 cGy (180 cGy twice daily) days –4 to –1
Anand et al. BBMT 2017[38]	Duke University, USA	• Thiotepa 5 mg/kg/day days –11 to –10 • Fudarabine 40 mg/m^2/day per day i.v. on days –5 to –2 • Total body irradiation 1350 cGy (150 cGy twice daily) on days –9 to –5
Sanz et al. BMT 2012[36]	University of Valencia, Spain	• Thiotepa 5 mg/kg/day on days –7 and –6 • Busulfan 3.2 mg/kg/day as a single daily dose on days –5 to –3, adjusted in patients weighing <34 kg • Fudarabine 50 mg/m^2/day on days –5 to –3 • Rabbit ATG 2 mg/kg/day on days –5 to –2.
Atsuta et al. Blood 2009[161]	University of Tokyo, Japan	• Cyclophosphamide 60 mg/kg/day days –4 and –3 • Total body irradiation 1200 cGy day –9 to –7 • Cytarabine 3 g/m^2 twice daily days –6 and –5 • Granulocyte colony-stimulating factor 5 μg/kg continuous intravenous infusion, from 12 h prior to start cytarabine stopping after the last dose
Reduced Intensity and Non-Myeloablative Regimens		
Brunstein et al. Blood 2007[33]	University of Minnesota, USA[a]	• Cyclophosphamide 50 mg/kg/day day –6 • Fludarabine 30–50 mg/m^2/day days –6 to –2 • Total body irradiation 200 cGy day –1
Ponce et al. Blood 2013[37]	Memorial Sloan Kettering Cancer Center, USA	• Cyclophosphamide 50 mg/kg/day day –6 • Fludarabine 30 mg/m^2/day days –6 to –2 • Thiotepa 5 mg/kg/day days –5 and –4 • Total body irradiation 400 cGy (200 cGy daily) day –2 and –1
DeFilipp et al. BMT 2020[47]	Dana Farber Cancer Institute and Massachusetts General Hospital, USA	• Fudarabine 30 mg/m^2/day days –7 to –2 • Melphalan 100 mg/m^2/day day –1 • Total body radiation 200 cGy day 0
Ballen et al. BBMT 2007[39]	Dana Farber Cancer Institute and Massachusetts General Hospital, USA	• Fudarabine 30 mg/m^2/day days –8 to –3 • Melphalan 100 mg/m^2/day day –2 • Rabbit ATG 1.5 mg/kg/day days –7, –5, –3, and –1
Ciurea et al. Leuk Lymphoma 2012[40]	MD Anderson Cancer Center, USA	• Melphalan 140 mg/m^2 on day –8 • Thiotepa 10 mg/kg (day –7), fludarabine 160 mg/m^2 over 4 days (days –6 to –3) and rabbit antithymocyte globulin (ATG) 1.25 mg/kg (day –4) and 1.75 mg/kg (day –3)
Yamamoto et al. BBMT 2016[46]	Toranomon Hospital, Japan	• Fudarabine 30 mg/m^2/day days –7 to –2 • Melphalan 40 mg/m^2/day days –3 and –2 • Busulfan 3.2 mg/kg 4 times daily, days –7 to –4
Deeg et al. BBMT 2018[45]	Fred Hutchinson Cancer Research Center, USA	• Treosulfan, 14 g/m^2/day on days –6 to –4 • Fludarabine, 30 mg/m^2/day on days –6 to –2 • Total body radiation 200 cGy day 0

[a] Horse ATG 15 mg/kg twice daily days –6 to –4, if no recent immunosuppressive chemotherapy or previous autologous transplant,
ATG, Anti-thymocyte globulin.



Suitable cord blood graft available
Need to identify suitable back-up graft?
Age
Acceptable and controlled comorbidities
Good social support system
Diagnosis suitable for CB transplantation
Intensity and type of condition regimen
Proceed to CB transplantation
Advanced age
Multiple or uncontrolled comorbidities
Poor social support system
Diagnosis unsuitable for CB transplantation
Discuss with patient and consider alternative treatment approach

Figure 108.2 CONSIDERING PATIENT SUITABILITY FOR CORD BLOOD TRANSPLANTATION. *CB*, Cord blood.

for CBT significantly improved engraftment in general and was key in extending this donor type to adults in the myeloablative and reduced intensity settings.[11,33] Table 108.1 summarizes some of the conditioning regimens used in CBT. It is important to keep in mind that in CBT, the conditioning regimen is part of the platform and that success using this donor type is a full package that includes graft selection, patient evaluation, and supportive care, which depends heavily on center experience (Fig. 108.2).

Myeloablative Conditioning

In children, the myeloablative regimen with cyclophosphamide (CY), FLU, and 1200 to 1320 Gy total body irradiation (TBI; TCF regimen) developed by the University of Minnesota has been widely used and has resulted in high rates of engraftment.[11] In a recent multicenter study, this conditioning regimen improved outcomes among children and young adults with acute leukemia,[9] as evidenced by a comparison with chemotherapy only and non-FLU-containing TBI regimens.[10] Taken together, these data support the use of TCF as a preferred regimen for patients with leukemia who are candidates for MA.

Given that this is the main indication for allogeneic transplantation in this age group, it was extrapolated for other conditions. In adults, the TCF regimen has also been shown to result in high rates of engraftment and progression-free survival compared to transplantation using other donor types.[34] At least in part, the long-term disease control seems to be driven by a potent graft versus leukemia effect.[3] The use of this myeloablative regimen in centers with less experience in CBT has proved challenging.[35] This led to increased interest in reduced toxicity FLU-based regimens with thiotepa. These regimens have been shown to produce very promising outcomes in single[36] and double[37,38] CBT and potentially better applicability (see Table 108.1). An advantage of these regimens is the ability to extend intensive conditioning regimens to older fit patients, potentially improving outcomes.

Reduced-Intensity and Non-Myeloablative Conditioning

Reduced-intensity and non-myeloablative conditioning regimens are mostly used for the treatment of adult patients who are older or those who have comorbid conditions that would otherwise increase their risk of TRM. Similar to the myeloablative setting, FLU is a critical component of these conditioning regimens. Non-myeloablative conditioning consisting of CY 50 mg/kg, FLU 150 to 200 mg/m^2, and TBI 200 cGy (Cy-Flu-TBI-200) described by the University of Minnesota is the most commonly used regimen.[33] Other reduced-intensity nonmyeloablative conditioning regimens have been described,[39–41] but a retrospective registry-based comparison suggested that Cy-Flu-TBI-200 resulted in superior long-term outcomes.[42] However, the reported outcomes from the centers that developed each conditioning regimen are very similar. Thus, center experience with a treatment platform that includes conditioning regimen, immune suppression, and supportive care impacts outcomes.

In contrast to myeloablative conditioning regimens, indications for CBT transplantation using a reduced-intensity or a non-myeloablative conditioning regimen include not only acute leukemia, but also chronic leukemia, myelodysplasia, and lymphomas. To facilitate engraftment in these older patients whose disease was not treated with potent immunosuppressive chemotherapy, ATG was added to the conditioning regimens to improve engraftment. However, ATG was associated with a higher risk of viral reactivations, post-transplant lymphoproliferative disorders, and slower immune reconstitution.[43,44] Thus, investigators have developed ATG-free regimens by replacing it with thiotepa, treosulfan, busulfan, or TBI.[36,45–47] A new strategy dosing the ATG based on the absolute lymphocyte count may allow for a better therapeutic window of this drug as part of the conditioning regimens while allowing adequate immune reconstitution after UCB transplantation.[48,49]

Conditioning Regimens for Non-Malignant Disease in Children

The indications of UCB transplantation in children extend to nonmalignant diseases such as hemoglobinopathies, immune deficiencies, marrow failure syndromes, and metabolic diseases. In these diseases, there is a need to balance the intensity of the immunosuppression with specific disease manifestations that could impact the recipient's tolerance of toxic drugs commonly used in conditioning regimens and TBI. Examples of such diseases include Fanconi Anemia and Dyskeratosis Congenita. In these situations, there is increased sensitivity to adverse events of chemotherapy and radiation.[50] To be immune ablative and reduce the risk of graft rejection, these regimens often use in vivo T cell depletion with ATG or alemtuzumab.[51] Thus, in this setting, the conditioning regimen will be somewhat disease-specific and is determined by the center's expertise. It is challenging to present specific outcomes about conditioning regimens because, as mentioned before, the outcomes depend on the whole transplant "package" adopted by the transplant center.[51]

GRAFT-VERSUS-HOST DISEASE IN CORD BLOOD TRANSPLANTATION

The growth of the CB inventory has allowed for the identification of larger and better HLA-matched CB units, in particular in children. Nonetheless, most CB grafts remain HLA-mismatched to the patients, and many adults continue to require double CB grafts. Despite the presence of HLA-mismatches, there is a relatively low incidence of acute and chronic GVHD (cGVHD) after CB transplantation, as compared to HLA-mismatched grafts in other donor types.[34,52–54] The distribution of the severity of cGVHD manifestations after CBT does not differ from other donor types, with approximately two-thirds having mild to moderate symptoms.[54] There seems to be a lower risk of development of cutaneous sclerosis after CBT as compared to other donor types,[54,55] with late acute GVHD (aGVHD) being a frequent clinical presentation of GVHD after CBT.[55] Recipients of CBT also seem to have superior GVHD-free, relapse-free survival as compared to other donor types.[54] The risk of aGVHD in single CBT ranges from 10% to 50% with higher incidences observed in adults receiving CB units that are more HLA-mismatched, as discussed in this section. Studies found no impact of the degree of HLA-mismatch when conventional HLA-matching criteria are considered in studying the risk of GVHD after CBT.[56] More recently, studies in single CBT evaluated the impact of allele level HLA-matching and found an approximately 1.5-fold relative increase in the risk of aGVHD with ≥2 allele level mismatches, but no effect on cGVHD.[18] As compared to single CBT, double CBT has overcome the barrier of low cell dose in single CBT and expanded its use to more adult recipients, but it resulted in a higher incidence of aGVHD and cGVHD, as compared to single CBT.[9,12,37] After double CBT, the incidence of acute grades II to IV GVHD ranges from 25% to 75% and cGVHD from 20% to 50%. When considering the historical HLA-matching practice (HLA-A and -B at the antigen level and -DRB1 at the allele level), there is no obvious effect on the risk of GVHD when there are up to 2 HLA-mismatches. In contrast to single CBT, the effect of allele level matching at 8 to 10 loci is less clear.[17,57] This discrepancy may result from differences in patient population and numbers, institutional supportive care, and immunosuppression practice but is not limiting to the efficacy of double CBT. Maintaining higher serum levels of calcineurin inhibitors (CNI) and administration of higher doses of MMF seems to provide superior GVHD prophylaxis in double CBT, as discussed in the following section.

Graft-Versus-Host Disease Prophylaxis in Cord Blood Transplantation

GVHD prophylactic regimens have changed, and currently, the most commonly used regimen used in the United States is the combination of a CNI and MMF, which has largely replaced the short course of corticosteroids. This combination is currently used both in adults and children, with myeloablative and reduced-intensity conditioning regimens and with single and double CB transplantation. The choice of the CNI, whether tacrolimus or cyclosporine-A, is driven by institutional preference. However, data show that keeping the cyclosporine-A level in the upper range of the target serum level of 200 to 400 ng/mL in the first 30 days after CB transplantation results in a lower risk of GVHD.[58] Based on pharmacokinetic studies suggesting suboptimal serum levels of mycophenolic acid (MPA), some centers adopted either a higher dose of MMF (from 2 g/day to 3 g/day) or monitored MPA levels resulting in higher exposure to MPA and lower risk of aGVHD.[59,60] The combination CNI with methotrexate (MTX), commonly used in sibling and unrelated donor (URD) transplantation, is also used in CB transplantation in Japan and to a lesser extent in Europe.[61] The CNI/MTX combination was associated with delayed engraftment after CB transplantation, and further studies demonstrated that reduced dose and frequency of MTX (mini MTX) given at 5 to 10 mg/m^2 on days +1 and 5 to 7 mg/m^2 on days +3 and +6 improved engraftment, effectively suppressed GVHD, and reduced TRM.[62–64] Further reduction in the MTX to only days +1 and +3 resulted in an increased risk of aGVHD after CB transplantation.[63] Retrospective data suggest that in patients with acute leukemia receiving a myeloablative or reduced-intensity conditioning single-unit CBT, CNI plus MTX results in a lower incidence of grade III to IV aGVHD compared to CNI plus MMF.[65,66] ATG is still being used by some centers as part of the conditioning regimen to further ablate the recipient's immune system and improve engraftment rather than GVHD prophylaxis.[33] Registry data demonstrate that ATG reduces the incidence of aGVHD in single and double CB transplantation.[56] The effect of ATG in reducing the risk of GVHD is variable depending on dose, ATG source (rabbit or equine), and timing of administration in relation to the CB graft infusion. After being originally tested in matched related donor peripheral blood stem cell (PBSC) transplantation, the mammalian target of rapamycin (mTOR) inhibitor sirolimus in combination with tacrolimus was studied in reduced-intensity double CB transplantation.[67] In this study, sirolimus/tacrolimus immunosuppression resulted in remarkably low incidences of grade II–IV aGVHD (3 of 32 patients; 9.4%) and cGVHD (13%). Another group studied the combination of sirolimus and MMF in the non-myeloablative setting.[68] This combination was based on studies that involved the adoptive transfer of CB-derived regulatory T cells.[69,70] However, sirolimus/MMF alone resulted in similar rates of GVHD but was better tolerated with a lower overall incidence of infections and less renal toxicity, as compared to cyclosporine and MMF.[68] There was, however, a higher risk of HHV-6 reactivation and delayed engraftment, which may require foscarnet suppression. Neither sirolimus with tacrolimus nor MMF results have yet been reproduced by other groups.

Graft-Versus-Host Disease Outcomes in Cord Blood Transplantation

All-grade aGVHD occurs less frequently in mismatched CBT relative to URD transplantation.[34,71–73] Severe aGVHD after CBT is overall similar to that of matched URD transplantation.[74–76] The most commonly involved organs in all-grade aGVHD are skin and the gastrointestinal tract.[9,57,77] As compared to other donor sources, aGVHD is reported to be overall more responsive to first-line immunosuppressive therapies, with a less detrimental impact on overall survival.[53,57,78] The incidence of overall and severe cGVHD is lower in CBT than in URD and matched sibling transplants.[34,52,53,57] Additionally, the median time to discontinuation of immunosuppression and immune suppression burden including late infections are reported to be lower in CBT than URD peripheral blood transplants with increased corticosteroid responsiveness.[52,79]

OUTCOMES OF CORD BLOOD TRANSPLANTATION

Acute Leukemia and Myelodysplastic Syndrome

The use of CB transplantation has been successfully used worldwide for the treatment of patients with acute leukemia and myelodysplastic syndromes (MDS), both in adult and pediatric patients. In children, most CB transplantation has been after myeloablative conditioning regimens, while in the adult population, a large proportion of patients have received reduced-intensity or non-myeloablative conditioning regimens.

Prospective and retrospective studies in children undergoing CB transplantation for acute leukemia and MDS have found that the probabilities of overall survival and disease-free survival range between 65% to 73% and 47% to 70%, respectively.[9,10,80] In a prospective randomized trial that compared single and double CB transplantation in children, the better outcomes were in children with

AML, self-reported white race[9] and confirmed the positive effect of HLA matching on leukemia-free survival.[9,81] This prospective study observed no difference in the outcomes between recipients of single or double CB grafts as previously reported,[82] but data suggest better disease control among children with minimal residual disease receiving a double CB graft.[83] As children who receive less well HLA-matched CB grafts seem to have a lower risk of relapse,[9] it is possible that better disease control was driven by the lower degree of HLA-matching observed in those patients who require a double CB graft. Recent data demonstrate that the TCF conditioning regimen (see the Conditioning Regimens section) was, at least in part, the main reason for the improved outcomes of children receiving CBT transplants over time.[10,84] The use of a novel treosulfan-containing regimen in children with AML and MDS seems to also result in excellent disease control and survival.[85] Taken together, these data support CB as an effective and valuable graft source in children with leukemia and MDS.

In adults, CB transplantation has also been extensively used for the treatment of leukemia and MDS, with outcomes that are similar to those of matched related and URD transplantations.[3,34,37,42,86–88] However, the long-term outcomes vary depending on the intensity of the conditioning regimen and patient population. In centers with extensive experience in CB transplantation, outcomes after myeloablative regimens and the more recently described myeloablative-reduced-toxicity (thiotepa- or melphalan-containing) regimens may result in overall survival of 50% to 73% and DFS of 45% to 68%.[3,34,37,38,47,89] In the myeloablative setting, there was also a suggestion of better disease control in patients who received CB grafts taken to transplantation with MRD+ disease.[3] It seems that a TBI-containing myeloablative regimen provided better disease control for patients with acute lymphoblastic leukemia, whereas TBI-containing and chemotherapy-only regimens were similarly effective in acute myeloid leukemia.[90] After non-myeloablative CB transplantation, the overall survival was 40% to 54% and PFS was 30% to 45%.[42,91,92] These outcomes are driven by a higher risk of relapse that ranges from 35% to 47%. Notably, in both myeloablative and non-myeloablative settings, the TRM after CB transplantation tended to be higher as compared to other donor types, at least in part, due to the longer time to neutrophil recovery and risk of infections.

Mature Lymphoid Malignancies

There is abundant evidence of the efficacy of CB transplantation for the treatment of mature lymphoid malignancies in the literature. However, a significant amount of these data are combined in reports of CB for the treatment of hematological malignancies and numerous case reports. Most of the data on these diseases are in adult patients. Registry-based studies of CB transplantation for mature lymphoid malignancies found an overall survival of 41% to 56%, progression-free survival of 31% to 41%, incidence of relapse of 28% to 30%, and non-relapse mortality of 29% to 37%.[93,94] In these reports, survival and mortality were similar to that of matched URD transplantation even after adjusting for relevant variables. In another report limited to diffuse large cell B-cell lymphoma, 4-year overall survival was 27%, relapse-free survival was 27%, incidence of relapse was 59%, and non-relapse mortality was 17%.[95] Outcomes were better in patients in partial or complete remission and in those with a longer time from diagnosis to transplantation. Although this study had a relatively small number of patients, the results were similar to those of BM transplantation, and the outcomes reflect the high-risk nature of treated patients. Data on Hodgkin lymphoma showed that overall survival was 46% to 80%, progression-free survival was 26% to 53%, the incidence of relapse was 36% to 44%, and non-relapse mortality was 11% to 30%.[96–98] In multivariate analysis, patients in complete or partial remission and those who received a TCF non-myeloablative conditioning regimen had better survival.[97] Although chronic lymphocytic leukemia is less often an indication of allogeneic transplantation, CB has also been shown to provide long-term survival for those with advanced or high-risk disease (i.e., mutated *p53*). In a series on chronic lymphocytic leukemia from EBMT, the overall survival, progression-free survival, relapse, non-relapse mortality rates were 16%, 39%, 54%, and 45%, respectively.[99] Patients who were CMV seronegative, had FLU-sensitive disease, received less than three previous lines of chemotherapy, and received a non-myeloablative regimen with low-dose TBI regimens had better overall survival. In a report on adult T-cell leukemia/lymphoma (ATLL), CB transplantation resulted in an overall lower probability of overall survival as compared to unrelated BM transplantation.[100] The difference was driven by higher non-relapse mortality in the low-risk disease group (27% vs. 39%). However, in ATLL patients with intermediate and high-risk disease, the efficacy of CB transplantation was similar to unrelated BM transplantation. Recent registry-based studies have found that patients with lymphoma undergoing CB transplantation had similar relapse risk, but somewhat lower progression-free and overall survival, as compared to partially matched related donor transplantation.[94,96] The difference in outcomes resulted from the remarkably low non-relapse mortality observed among recipients of partially matched related donor transplantation. Nonetheless, the data above support the use of CB for patients with lymphoid malignancies who lack other donors.

Non-Malignant Diseases in Pediatrics

CB has been shown to be a valuable alternative donor type for children with non-malignant diseases who lack a matched related or URD.[51] In diseases that require urgent transplantation to avoid organ damage and complications or death from the underlying disease (e.g., severe combined immunodeficiency, Hurler's syndrome, adrenoleukodystrophy, and Krabbe's disease), CB offers a readily available source of stem cells.[7,101–103] While it may not always reverse the disease manifestations, similar to other donor types, CB may provide stabilization of symptoms and avoid further disease progression. Patients with Wiskott–Aldrich syndrome transplanted before 2 years of age have an OS of 75%,[104] and those with Fanconi anemia with no history of opportunistic infections may have survival over 90%.[50] While not as successful in about half of children with hereditary hemophagocytic syndrome and osteopetrosis, CB transplantation may achieve long-term survival.[105,106] Advances in the immunosuppressive properties of conditioning regimens have allowed for better outcomes of patients receiving CB grafts for the treatment of severe acquired aplastic anemia (SAA). One approach that has resulted in a 2-year survival of 84% in patients with SAA involved the selection of a single or double CB graft with a minimum TNC dose of 4.0×10^7/kg and a conditioning regimen with CY 30 mg/kg and FLU 30 mg/m^2 daily for 4 days, rabbit total ATG 5.0 mg/kg, and TBI 200 cGy.[107] Thus, such a strategy could be considered for adults with SAA but is most appropriate if done in the context of a clinical trial. However, the best outcomes with CB transplantation in these complex and very different diseases are achieved with adequate CB graft selection, tailored conditioning, supportive care, and a transplant center with both CB transplantation and target disease experience.

OTHER DISEASES

Multiple myeloma has been a progressively less frequent indication of allogeneic transplantation, and the small number of patients treated in individual centers have been reported in series with other hematological malignancies. In registry studies, the progression-free survival and overall survival were 13% to 24% and 15% to 40%, respectively.[108,109] Interestingly, patients with multiple myeloma undergoing planned tandem autologous transplantation followed by CB transplantation had an overall survival of 46%.[109] The use of ATG, high-risk cytogenetics, and chemotherapy-refractory multiple myeloma were predictors of worse survival.[108,109] CB has been used as the graft source for chronic myeloid leukemia and other myeloproliferative diseases. In these less frequent indications of allogeneic transplantation, if CB transplantation is considered the best option for the patient, it should be considered in a clinical trial and/or in consultation with a center experienced with this donor type.

OUTCOMES OF CORD BLOOD RELATIVE TO OTHER DONOR TYPES

Numerous studies have compared the outcomes of CB to other donor types in the myeloablative and non-myeloablative settings, pediatric and adult patients, and leukemia and lymphoid malignancies. Selected studies on this topic published in the last decade (2010 to 2020) are summarized in Tables 108.2, 108.3, and 108.4. Overall, earlier in the last decade, these studies showed that CB leads to outcomes similar to other donor types that at the time were mostly matched siblings and matched and mismatched URDs. As advances in supportive care, HLA typing, donor selection, and GVHD prophylaxis were made, there has been a shift in practices with renewed interest in mismatched unrelated and partially matched related donors (haploidentical donors) and a reduction in the utilization of CB as a graft source in HCT. While recent studies in adults showed that CB may have similar progression-free and disease-free survival after HCT as compared to haploidentical donor transplantation, the latter seems to provide better overall survival, at least in part, because of very low non-relapse mortality.[92,94,110–112] Many factors influence the differences observed in studies comparing CB to other donor types including, but not limited to, patient population and source of the report. In children, for example, CB transplantation is a well-established practice and results in outcomes similar to other donor types (see Table 108.4).[16,80,87,113–116] In contrast, in older adults, CB transplantation has to be considered with caution as this patient population was found to have higher overall mortality, possibly related to a combination of longer engraftment time, more frequent presence of co-morbidities, and disease characteristics (see Table 108.3).[117–119] Notably, reports from a center with a focus on CB as an alternative donor type for HCT consistently showed outcomes similar to other donor types, demonstrating the importance of transplant center expertise in the outcomes of CB transplantation (see Table 108.2).[3,34,86,120] In summary, in the context of smaller families, issues with donor availability, and the presence of donor-specific antibodies, CB remains a valuable donor option for HCT for those patients who lack a matched donor.

STRATEGIES TO IMPROVE CORD BLOOD TRANSPLANTATION OUTCOMES

To reduce the longer time to neutrophil recovery after CB transplantation as compared to BM or PBSC transplantation, numerous strategies have been studied. The reader may refer to a review on this topic for more details.[121,122] We limited this section to more contemporaneous strategies.

Ex Vivo Cord Blood Expansion

The demonstration of the safety of the double CB graft platform set the stage for most of the recent studies in ex vivo CB expansion. In phase 1/2 studies, these strategies used myeloablative or myeloablative-reduced-toxicity conditioning regimens on the double CB platform, where one unit was ex vivo expanded and the other unit was infused unmanipulated as a safety measure. Notably, in contrast with previous strategies in which the ex vivo expanded product was CD3+ depleted, more recent strategies saved and co-infused CD3+ cells derived from the ex vivo expanded unit at the time of transplantation in order to establish long-term chimerism of the ex vivo expanded CB unit; these studies are summarized in Table 108.5. The strategy using nicotinamide (omidubicel) in combination with cytokines is further along in development, and investigators recently completed a randomized phase 3 study comparing the best CB graft available.[123,124] The primary endpoint of this study was time to neutrophil recovery, and while it took 21 days for production, it seems to provide reproducible expansion. The strategy using an SR-1 inhibitor completed phase 1/2 and is currently being evaluated in a phase 2 expansion cohort study[125] testing a cryopreserved product; this strategy seems to provide robust ex vivo expansion. The UM171-based strategy that recently completed phase 1/2 and a small phase 2 expansion phase is the platform with the shortest ex vivo culture time, potentially allowing the culture to occur while the patient is receiving the conditioning regimen.[126] The copper chelator tetraethylenepentamine (carlecortemcel-L) also provided robust expansion,[127] but the time to neutrophil recovery was similar to the 24 to 26 days of conventional single or double CB transplantation. However, in this platform, they only ex vivo expanded a portion of a single CB unit, and it could be speculated that if the investigators expanded the whole unit, time to neutrophil recovery could have been shorter. In summary, there are very promising ex vivo CB expansion platforms in development, and each has different strengths. It is possible that we will have an FDA-approved product in the next 1 to 2 years.

Improving Homing of Cord Blood

One of the strategies pursued in improving engraftment after CB was to improve the homing efficiency of the reduced number of progenitor and stem cells contained in CB units, as compared to BM and PBSC grafts. In a phase 1 study, investigators tested dimethyl prostaglandin E2 (dmPGE2), which had been shown to modulate homeostasis and engraftment in in vitro and in vivo models.[128] The study in the double CB setting in which only one of the CB units was primed with dmPGE2 demonstrated the safety of the strategy, observed a shorter time to neutrophil recovery as compared to historical data (17 vs. 21 days), and found skewed single-unit predominance toward the primed unit. These promising results set the stage for a multicenter phase 2 study that has been completed and is pending reporting. Another group hypothesized that treating one of two CB units composing the graft with fucosyltransferase-VI and guanosine diphosphate fucose would result in higher fucosylation of selectins, resulting in improved homing and hematopoietic recovery after CB transplantation.[129] This study also observed a shorter time to neutrophil and platelet recovery after CB transplantation. This group is also studying fucosylation to improve homing of other cell populations, such as regulatory T cells.[130] In contrast to other strategies that primed or treated the CB ex vivo, one group of investigators administered sitagliptin to the patient; sitagliptin is a dipeptidyl peptidase-4 (DPP-4) inhibitor that prevents the cleavage of SDF1α, allowing for interaction with CXCR4, which is critical for stem cell homing.[131,132] This approach was studied in the single CB graft setting. After a dose-finding study,[131] a phase 2 study demonstrated inhibition of DPP-4 in the plasma and observed time to neutrophil recovery of 19 days. While alone these strategies seem to have only a modest effect, it is possible that they could be combined with ex vivo CB expansion for additive or synergistic effects that could result in better neutrophil recovery and reduce the risk of graft rejection.

Combination of Cord Blood and Haploidentical Donor

The combination of a single CB graft with a CD34+ selected haploidentical PBSC was studied initially in the myeloablative setting[133] and more recently in the non-myeloablative setting.[134] The short-term goal is to temporarily bridge the period of neutropenia with neutrophils derived from the haploidentical donor myeloid progenitors. The ultimate goal is for the haploidentical graft that is lymphocyte depleted to be rejected by the CB, which will establish chimerism and long-term hematopoiesis. Studies in this platform used CD34+ immunomagnetic selection of granulocyte colony-stimulating factor mobilized PBSCs with the goal of obtaining a graft containing 2.5 to 3×10^6 CD34+ cells/kg and less than 1×10^4 CD3+ cells/kg.[133]

ALL, Acute lymphoblastic leukemia; *AML*, acute myeloid leukemia; *BM*, bone marrow; *CB*, cord blood; *DFS*, disease-free survival; *dUCB*, double umbilical cord blood; *GRFS*, graft-vs-host and relapse-free survival; *HR*, hazard ratio; *MAC*, myeloablative conditioning; *MDS*, myelodysplastic syndrome; *MRD*, minimal residual disease; *NA*, not available; *NMA*, nonmyeloablative; *NRM*, non-relapse mortality; *OS*, overall survival; *PBSC*, peripheral blood stem cells; *PFS*, progression-free survival; *RIC*, reduced-intensity conditioning; *RR*, relative risk; *TRM*, treatment-related mortality; *URD*, unrelated donor.

The CD34+ selected cell dose was capped to reduce the risk of long-term engraftment of the haploidentical graft. Using this strategy in the myeloablative setting, the median time to neutrophil engraftment was 12 days with 95% of patients engrafted with a CB graft by 40 days after transplantation. Platelet engraftment occurred at a median of 36 days with a 78% cumulative incidence of engraftment by day 100. Cumulative incidence of grade II to IV aGVHD and cGVHD were both 21%. Overall survival with 60 months of median follow-up was estimated at 44%.[133] In the non-myeloablative setting, the times to neutrophil and platelet recovery were 11 days and 19 days, respectively. Acute and chronic GVHD occurred at rates of 25% and 5%, respectively, and estimated survival at 1 year was 55%.[134] Notably, in the non-myeloablative setting, a small number of patients had haploidentical donor-derived long-term hematopoiesis instead of engraftment of the CB graft. This combination is valuable and promising and seems to achieve results similar to matched URD transplantation but requires an institution able to perform the immunomagnetic selection.[135]

TABLE 108.4 Studies Comparing the Outcomes of Transplantation With Cord Blood and Other Donor Types in Pediatric Patients—cont'd

Reference	Diseases	Conditioning Intensity	Donor Type	OS	DFS/PFS	GRFS	TRM/NRM	Relapse	Outcome Years
			MSD ($n = 61$) vs. Urd 7-8/8 BM ($n = 73$)	0.67 (1.0)	0.83 (1.0)	0.67 (.73)	1.1 (1.0)	0.71 (1.0)	
			MSD ($n = 61$) vs. Single CB ($n = 122$)	0.67 (1.0)	0.77 (1.0)	1.1 (.65)	0.67 (1.0)	1.2 (1.0)	
			MSD ($n = 61$) vs. Double CB ($n = 61$)	0.43 (.091)	0.56 (0.406)	1 (.95)	0.42 (.497)	0.91 (1.0)	

ALL, Acute lymphoblastic leukemia; *AML*, acute myeloid leukemia; *BM*, bone marrow; *CB*, cord blood; *DFS*, disease-free survival; *dUCB*, double umbilical cord blood; GRFS, graft-vs-host and relapse-free survival; *HR*, hazard ratio; *MAC*, myeloablative conditioning; *MDS*, myelodysplastic syndrome; *MRD*, minimal residual disease; *NA*, not available; *NMA*, nonmyeloablative; *NRM*, non-relapse mortality; *OS*, overall survival; *PBSC*, peripheral blood stem cells; *PFS*, progression-free survival; *RIC*, reduced-intensity conditioning; *RR*, relative risk; *TRM*, treatment-related mortality; *URD*, unrelated donor.

TABLE 108.5 Summary of Selected Ex Vivo Expansion Platforms

Reference	Strategy Type	Reagent Class	Research Phases Completed	Time to Complete Ex Vivo Expansion	Median CD34+ Expansion	Minimum Required TNC for Expanded CB Unit	Median Time to ANC Engraftment	Median Time to PLT Engraftment
Horwitz et al. JCO 2019[123]	Nicotinamide (Omidubicel)	Amide form of vitamin B_3 (niacin)	Phase 1 Phase 2 Phase 3 (recently completed)	21 days	33-fold	1.5 × 10e7/kg	12 days	34 days
Wagner et al. Cell Stem Cell 2016[125]	SR1-inhibitor MGTA-456 (former HSC835)	Aryl hydrocarbon receptor inhibitor	Phase 1/2 Phase 2 (ongoing extension)	15 days	330-fold	1.5 × 10e7/kg	15 days	49 days
Cohen et al. Lancet Haematol 2020[126]	UM171	Pyrimido-indole derivative	Phase 1/2	7 days	28-fold	Phase 1: 2.0 ×10e7/kg Phase 2: 1.5 ×10e7/kg	18 days	42 days
Stiff et al. BBMT 2018[127]	Carlecortemcel-L	Copper chelator tetraethylenepentamine	Phase 1/2	22 days	90-fold	×10e7/kg In dual cryo bags	21 days	54 days

ALL, Acute lymphoblastic leukemia; *AML*, acute myeloid leukemia; *BM*, bone marrow; *CB*, cord blood; *DFS*, disease-free survival; *dUCB*, double umbilical cord blood; *GRFS*, graft-vs-host and relapse-free survival; *HR*, hazard ratio; *MAC*, myeloablative conditioning; *MDS*, myelodysplastic syndrome; *MRD*, minimal residual disease; *NA*, not available; *NMA*, nonmyeloablative; *NRM*, non-relapse mortality; *OS*, overall survival; *PBSC*, peripheral blood stem cells; *PFS*, progression-free survival; *RIC*, reduced-intensity conditioning; *RR*, relative risk; *TRM*, treatment-related mortality; *URD*, unrelated donor.

SUPPORTIVE CARE IN CORD BLOOD TRANSPLANTATION

While most supportive care measures used after hematopoietic SCT are similar to other donor types, infection prophylaxis and growth factor support require special attention after CB transplantation.

Infection Prophylaxis

Cytomegalovirus (CMV) reactivation is a frequent event after CB transplantation, and weekly monitoring and preemptive therapy is a mandatory practice to avoid CMV organ disease. The incidence of reactivation in CMV-seropositive patients using PCR ranges from 50% to 100% and typically occurs in the first 3 months after CB transplantation. The sensitivity of the PCR and viral copy number threshold to start preemptive therapy varies depending on the institution. While there has been a suggestion that patients who have CMV reactivation may be protected from relapse,[136,137] the treatment of CMV reactivation early after CB transplantation is challenging because of the potential morbidity and need for hospitalization caused by anti-CMV therapy complications, namely myelosuppression induced by ganciclovir and electrolyte disturbances and kidney injury caused by foscarnet. Thus, centers with expertise in CB transplantation pursue some form of CMV suppressive therapy,[138–141] and many centers have now adopted letermovir CMV prophylaxis for CMV-positive patients undergoing CB transplantation.[142]

Epstein-Barr virus (EBV) reactivation after allogeneic transplantation is most frequent in those receiving HLA mismatched grafts, when the donor is unrelated, and with the use of T cell-depleting agents or techniques (e.g., ATG, CD34+ selection). Not surprisingly, EBV reactivation may be seen in approximately 25% of patients after CB transplantation, with progression to post-transplant lymphoproliferative disease (PTLD) in 10% to 20% of patients.[43,44,143] Once PTLD is established, the prognosis is poor.[43,143] Especially when using ATG as part of the CB transplantation conditioning regimen, monitoring for EBV viremia and administering preemptive therapy with rituximab has been shown to reduce the risk of progression to PTLD.[144] More recently, administration of rituximab pre-CB transplantation has also been shown to be a potential approach in reducing the risk of EBV PTLD with this donor type.[145]

Human herpesvirus-6 (HHV-6) reactivation seems to be a frequent event typically happening 4 to 6 weeks after CB transplantation.[146–148] The more significant clinical manifestations of HHV-6 reactivation after CB transplantation include a maculopapular rash, fevers, delayed hematopoietic count recovery/graft failure, and limbic encephalitis.[149–151] Notably, the frequency of limbic encephalitis varies from center to center, and the reasons for this variation are not completely understood.[152] It is possible that those receiving sirolimus-based GVHD prophylaxis are at higher risk of HHV-6 reactivation.[68] The potentially devastating impact of graft failure and encephalitis led to attempts at prophylactic therapy or monitoring HHV-6 reactivation and instituting preemptive therapy with either foscarnet or valganciclovir.[153–155] The toxicity of these two antivirals has been challenging, and these prophylactic strategies have not been shown to prevent limbic encephalitis.[154] The impact of HHV-6 therapy in preventing delayed engraftment and graft failure is yet to be determined. It is also unclear what viral load should be considered before beginning any therapy. Thus, patients undergoing CB transplantation should be monitored for HHV-6 reactivation every 1 to 2 weeks. The detection of a positive or rising viral load needs to be considered in the context of PCR test sensitivity, sample (whole blood vs. plasma), and methodology of HHV-6 testing as very high viral load may represent DNA viral integration rather than HHV-6 reactivation. Therapy with foscarnet or valganciclovir should be considered in those patients with rising HHV-6 viral load and symptoms (e.g., rash, fevers, slow hematopoietic recovery, and limbic encephalitis) and take into account the clinical context (e.g., pancytopenia and kidney function). Virus-specific T cells are currently under investigation for this indication (NCT02108522).

Antifungal and antibacterial prophylaxis is recommended to all patients undergoing CB transplantation and follows the clinical practice applied to other donor types. Antibacterial prophylaxis is typically delivered until neutrophil recovery, and fluoroquinolones have been primarily used. While fluconazole is an acceptable antifungal prophylaxis, patients who have a history of fungal infection or chest CT scan changes suggestive of fungal infection should be considered for anti-mold prophylaxis with micafungin[156] or micafungin followed by voriconazole.[157] In patients who initially receive fluconazole prophylaxis and have slow count recovery and fevers after CB transplantation, advancing anti-fungal coverage to target molds should be considered. Bacterial and *Pneumocystis jirovecii* prophylaxis should follow the same principles of other donor types.

Growth Factor Support

Most patients will receive GCSF support after undergoing CB transplantation. Dosing and route of administration follow the same standard of care of other donor types. The timing of initiation of GCSF varies based on institutional practice, clinical protocols, and availability, which may be limited or restricted in some countries. Most commonly, GCSF is started between days +1 and +7 after transplantation, but some centers will not start until at least 21 days with no evidence of white cell counts and/or neutrophil recovery. Considering the delay in hematologic recovery after CB as compared to other donor types, centers with CB expertise in the United States will start GCSF in the first-week post-transplantation and continue until neutrophil engraftment. As the time to platelet recovery is also longer after CB transplantation, leading to increased blood product utilization,[158] emerging data suggest that thrombopoietin receptor mimetics or agonists may be of value but should be used in the context of a clinical trial.[159,160] Careful attention to drug toxicity and viral infections are critical in reducing the risk of delayed hematopoietic recovery.

SUMMARY

There is a significant body of evidence to support CB as a valuable alternative source of hematopoietic cells for transplantation. Successful CB transplantation requires appropriate unit selection, adequate immunosuppressive conditioning regimen, effective GVHD prophylaxis, and adequate infection monitoring and management. Moreover, as experience also plays a role in the success of CB transplantation, less experienced centers are encouraged to access unit selection resources and reach out to a center with CB expertise for advice and guidance. In addition to better tolerated more intensive conditioning regimens, new CB expansion and homing enhancement methodologies are likely to improve the efficacy of this donor type.

CHAPTER 109

GRAFT-VERSUS-HOST DISEASE AND GRAFT-VERSUS-LEUKEMIA RESPONSES

Mary Riwes, James L. Ferrara, Pavan Reddy, and John M. Magenau

The ability of allogeneic hematopoietic cell transplantation (HCT) to cure certain hematologic malignancies is widely recognized. An important therapeutic aspect of HCT in eradicating malignant cells is the graft-versus-leukemia (GVL) effect. The importance of the GVL effect in allogeneic HCT has been recognized since the earliest experiments in stem cell transplantation. Forty years ago, Barnes and colleagues noted that leukemic mice treated with a subtherapeutic dose of radiation and a syngeneic (identical twin) graft transplant were more likely to relapse than mice given an allogeneic stem cell transplant. They hypothesized that the allogeneic graft contained cells with immune reactivity necessary for eradicating residual leukemia cells. They also noted that recipients of allogeneic grafts, although less likely to relapse, died of a “wasting syndrome” now recognized as graft-versus-host disease (GVHD). Thus, in addition to describing GVL, these experiments highlighted for the first time the intricate relationship between GVL and GVHD. Since these early experiments, both GVHD and the GVL effect have been studied extensively. This chapter reviews the pathophysiology, clinical features, and treatment of GVHD and summarizes current understanding of the relationships between GVHD and the GVL effect.

GRAFT-VERSUS-HOST DISEASE: CLINICAL AND PATHOLOGIC ASPECTS

Ten years after the work of Barnes and Loutit, Billingham formulated the requirements for the development of GVHD: the graft must contain immunologically competent cells, the recipient must express tissue antigens that are not present in the transplant donor, and the recipient must be incapable of mounting an effective response to destroy the transplanted cells. According to these criteria, GVHD can develop in various clinical settings when tissues containing immunocompetent cells (blood products, bone marrow, and some solid organs) are transferred between persons. The most common setting for the development of GVHD is following allogeneic HCT; without prophylactic immunosuppression, most allogeneic HCTs will be complicated by GVHD. GVHD is induced by mismatches between histocompatibility antigens between the donor and recipient. Matching of the major histocompatibility complex (MHC) antigens hastens engraftment and reduces the severity of GVHD. In humans, the MHC region lies on the short arm of chromosome 6 and is called the human leukocyte antigen (HLA) region. The HLA region is divided into two classes, class I and class II, each containing numerous gene loci that encode a large number of polymorphic alleles. MHC class I molecules are involved in the presentation of peptides to $CD8^+$ T cells, and class II molecules present peptides to $CD4^+$ T cells.

The determination of HLA types has become much more accurate with molecular techniques that replace earlier serologic or cellular methods. The average patient has a 25% chance of having an HLA match within his or her immediate family. Patients who lack an HLA-identical family member donor must seek an unrelated haploidentical or cord blood donor. In patients whose ancestry involves extensive interracial mixing, the chances of identifying an HLA identical donor are diminished. Using a population-based genetic model, it is estimated that 75% of Whites of European decent will have a high-resolution matched unrelated donor at the key major class 1 and class II loci; however, patients of African or South Asian ancestry have a less than 30% chance of identifying a similar pairing. Advances in the clinical application of haploidentical (partial HLA match) HCT have now expanded alternate options for ethnic groups disproportionately affected by limited access to unrelated donors.[1]

Despite HLA identity between a patient and donor, substantial numbers of patients still develop GVHD because of differences in minor histocompatibility antigens (MiHAs) that lie outside the HLA loci. Genome-wide arrays demonstrate that single nucleotide polymorphisms (SNPs), reflecting amino-acid coding differences between donor-recipient pairs, are themselves sufficient for producing clinical GVHD. For example, each 1% difference in SNPs resulted in 20% relative risk of developing grade III to IV GVHD.[2] Nonetheless, the identity of the relevant minor antigens that comprise differences in peptides that are expressed on the cell surface bound to specific HLA molecules has yet to be precisely elucidated.

Acute Graft-Versus-Host Disease

Acute GVHD typically occurs within 30 days of transplantation (in HLA-matched recipients receiving standard GVHD prophylaxis) but occurs in diminishing frequencies for up to 6 months.[3,4] The incidence ranges from less than 10% to more than 80%, depending on the degree of histoincompatibility between donor and recipient, the number of T cells in the graft, the patient’s age, and the GVHD prophylactic regimen. The principal target organs include the immune system, skin, liver, and intestine. GVHD occurs first and most commonly in the skin as a pruritic maculopapular rash, often involving the palms, soles, and ears; it can progress to total-body erythroderma, with bullae formation, rupture along the epidermal-dermal border, and desquamation in severe cases. Gastrointestinal (GI) and liver manifestations often appear later and rarely represent the first and only findings. Intestinal symptoms include anorexia, nausea, diarrhea (sometimes bloody), abdominal pain, and paralytic ileus. Liver dysfunction includes hyperbilirubinemia and increased serum alkaline phosphatase and aminotransferase values. Coagulation studies may become abnormal, and hepatic failure with ascites and encephalopathy may develop in severe cases. Hepatic GVHD can be distinguished from hepatic venoocclusive disease (VOD) by weight gain or pain in the right upper quadrant in the latter. Acute GVHD also results in the delayed recovery of immunocompetence. The clinical result is profound immunodeficiency and susceptibility to infections, often further accentuated by the immunosuppressive agents used to treat GVHD.

Pathologically, the sine qua non of acute GVHD is selective epithelial damage of target organs. The epidermis and hair follicles are damaged and sometimes destroyed. Small bile ducts are profoundly affected, with segmental disruption. The destruction of intestinal crypts results in mucosal ulcerations that may be either patchy or diffuse. Other epithelial surfaces, such as the conjunctivae, vagina, and esophagus, are less commonly involved. A peculiarity of GVHD histology is the early paucity of mononuclear cell infiltrates; however, as the disease progresses, the inflammatory component may be

sevier on April
ıghts reserved.

substantial. Studies that identified inflammatory cytokines as soluble mediators of GVHD have suggested that direct contact between target cells and lymphocytes is not always required (see following sections). GVHD lesions are not evenly distributed: in the skin, damage is prominent at the tip of rete ridges; in the intestine, at the base of the crypts; and in the liver, in the periductular epithelium. These areas all contain a high proportion of stem cells, giving rise to the idea that GVHD targets may be undifferentiated epithelial cells with primitive surface antigens.

The histologic severity of GVHD is at best semiquantitative in part due to inability to sample tissues in the small intestine, and consequently pathologic scores are not used to grade GVHD. Because it is often difficult to obtain an adequate tissue biopsy, and because it can be very difficult to distinguish GVHD from other post-HCT complications such as drug eruptions or infectious complications, the physician is left to use clinical judgment.

Standard grading systems generally include clinical changes in the skin, GI tract, liver, and performance status (Table 109.1). Although the severity of GVHD is often difficult to quantify, the overall maximal grade correlates with disease outcome: mild GVHD (grade I or II) is associated with little mortality, whereas higher grades are associated with significantly decreased survival. Refined staging methods that standardize diagnosis and clinical grading (Mount Sinai Acute GVHD International Consortium [MAGIC]) are becoming more widely adopted in clinical practice and research.[5] However, consistent across all clinical staging systems is the association between high-grade organ involvement (grade III to IV) or disease affecting multiple organs and increased mortality. Once severe GVHD is established, the likelihood of responding to treatment is less than 50% and patients are at twice the risk of succumbing to GVHD or its sequela than mild to moderate forms of disease.[6] Although GVHD remains a clinical diagnosis, recent advances in the use of biomarkers may improve diagnostic sensitivity or provide early prognostic information to inform primary therapy.

Clinical Features of Acute Graft-Versus-Host Disease

The clinical features, staging, and grading of acute GVHD are summarized in Tables 109.1 and 109.2. In a comprehensive review of patients receiving therapy for acute GVHD, Martin and colleagues found that 81% had skin involvement, 54% had GI involvement, and 50% had liver involvement at the initiation of therapy. After high-intensity (myeloablative) conditioning, acute GVHD generally occurs within 14 to 35 days of stem cell infusion. A rapid and severe form of GVHD may occur in patients with severe HLA mismatches and in patients who receive T cell–replete transplants without or with inadequate in vivo GVHD prophylaxis. Although such GVHD is sometimes called “hyperacute,” this term is misleading because it is pathophysiologically distinct from hyperacute rejection after solid organ allografting, which is due to preformed antibodies. This form of GVHD, which is manifested by fever, generalized erythroderma and desquamation, and often edema, typically occurs about 1 week after stem cell infusion and may be rapidly fatal. In patients receiving standard (in vivo) GVHD prophylaxis such as a combination of calcineurin inhibitors, such as cyclosporine (CSP) or tacrolimus, and methotrexate, the median onset of GVHD is typically 21 to 25 days after transplantation; however, after in vitro T-cell depletion of the graft, the onset of GVHD symptoms may be much later. Thus the findings of rash and diarrhea by 1 week after transplantation would very likely be due to ineffective prophylaxis and would be very unlikely with the use of calcineurin inhibitors or in vitro T-cell depletion of the stem cell inoculum. A less ominous syndrome of fever, rash, and fluid retention occurring in the first 1 to 2 weeks after stem cell infusion is the “engraftment syndrome.” These manifestations may be seen with either allogeneic or autologous transplantation. Although this syndrome’s pathophysiology is poorly understood, it is thought to be due to a wave of cytokine production as the graft starts to recover. These symptoms are related to, but distinct from, the “cytokine storm” of acute GVHD because there is no concomitant T cell–mediated attack. This syndrome responds immediately to steroids in most patients, and it typically presents earlier than acute GVHD.

TABLE 109.1 Clinical Manifestations and Staging of Acute Graft-Versus-Host Disease

Organ	Clinical Manifestations	Staging
Skin	Erythematous, maculopapular rash involving palms and soles; may become confluent Severe disease: bullae	Stage 1: <25% rash Stage 2: 25%–50% rash Stage 3: generalized erythroderma Stage 4: bullae
Liver	Painless jaundice with conjugated hyperbilirubinemia and increased alkaline phosphatase	Stage 1: bili 2–3 mg/dL Stage 2: bili 3.1–6 mg/dL Stage 3: bili 6.1–15 mg/dL Stage 4: bili >15 mg/dL
Gastrointestinal tract	Upper: nausea, vomiting, anorexia Lower: diarrhea, abdominal cramps, distension, ileus, bleeding	Stage 1: diarrhea > 500 mL/day Stage 2: diarrhea > 1000 mL/day Stage 3: diarrhea > 1500 mL/day Stage 4: ileus, bleeding

Skin is the most commonly affected organ (Fig. 109.1). In patients receiving transplants after myeloablative conditioning, the skin is usually the first organ involved, and GVHD often coincides with engraftment. However, the presentation of GVHD is more varied following nonmyeloablative transplants or donor lymphocyte infusions. The characteristic maculopapular rash can spread throughout the rest of the body but usually spares the scalp; it is often described as feeling like a sunburn, tight or pruritic. In severe cases the skin may blister and ulcerate. Histologic confirmation is critical to rule out drug reactions, viral infections, etc. but is optimally performed 1 to 2 days after the onset of rash in cases of patchy involvement. Pathologic findings that describe apoptosis at the base of dermal crypts is characteristic. Other features include dyskeratosis, exocytosis of lymphocytes, satellite lymphocytes adjacent to dyskeratotic epidermal keratinocytes, and dermal perivascular lymphocytic infiltration.

GI tract involvement of GVHD may present as nausea, vomiting, anorexia, diarrhea, and/or abdominal pain. It is a panintestinal process, often with differences in severity between the upper and lower GI tracts. Although gastroparesis is seen after bone marrow transplant, it is usually not associated with GVHD. The diarrhea of GVHD is secretory; in extreme cases significant GI blood loss may occur as a result of mucosal ulceration and is associated with a poor

TABLE 109.2 Glucksberg Criteria for Staging of Acute Graft-Versus-Host Disease[a]

Overall Grade	Skin	Liver		Gut
I	1–2	0		0
II	1–3	1	and/or	1
III	2–3	2–4	and/or	2–3
IV	2–4	2–4	and/or	2–4

[a] See Table 109.1 for individual organ staging. Traditionally, individual organs are staged without regard to attribution. However, the overall grade of graft-versus-host disease (GVHD) reflects the actual extent of GVHD. To achieve each overall grade, skin disease plus liver and/or gut involvement are required.

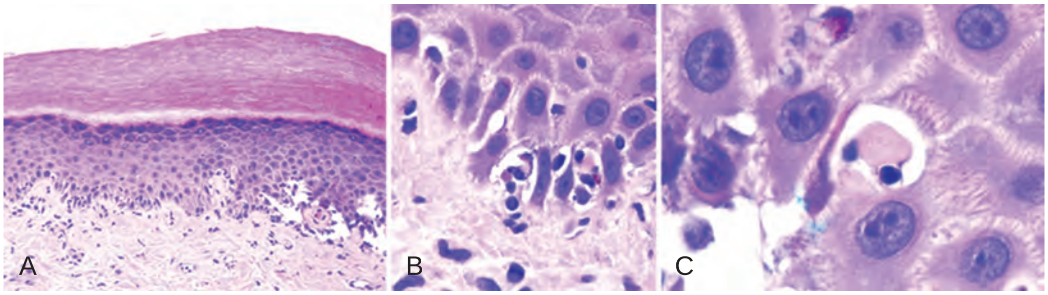

Figure 109.1 GRAFT-VERSUS-HOST DISEASE, SKIN BIOPSY. This 40-year-old man with a history of relapsed Hodgkin lymphoma was status postallogeneic stem cell transplant with donor lymphocyte infusion. He developed painful oral ulcers and a macular-papular rash on the arms, hand, and chest. The skin biopsy is from the palmar surface of the hand (A). It shows a scant lymphoid infiltrate in the dermis with a developing subepithelial blister *(right)*. There is basal vacuolar change (B) with single lymphocytes in the epithelium, as well as apoptotic keratinocyte accompanied by lymphocytes (B, and detail, C). *(Courtesy Vesna Petronic-Rosic and Mark Racz, University of Chicago.)*

prognosis. In advanced disease, diffuse, severe abdominal pain and distension is accompanied by voluminous diarrhea (>2 L/day).

Radiologic findings of the GI tract include luminal dilatation with thickening of the wall of the small bowel and air/fluid levels suggestive of an ileus on abdominal flat plates or small bowel series. Abdominal computed tomography may show the "ribbon" sign of diffuse thickening of the small bowel wall. Little correlation exists between the extent of disease and the appearance of mucosa on endoscopy, but mucosal sloughing is pathognomonic for severe disease. Nevertheless, some studies have shown that antral biopsies correlate well with the severity of GVHD in the duodenum and in the colon even when the presenting symptom is diarrhea. Histologic analysis of tissue is imperative to establish the diagnosis. The histologic features of GI GVHD are the presence of apoptotic bodies in the base of crypts, crypt abscesses, crypt loss, and flattening of the surface epithelium.

Liver function test abnormalities are common after bone marrow transplant and occur secondary to VOD, drug toxicity, viral infection, sepsis, iron overload, and other causes of extrahepatic biliary obstruction. The exact incidence of hepatic GVHD is unknown because many patients do not undergo liver biopsies. The development of jaundice or an increase in the alkaline phosphatase and bilirubin may be the initial features of acute GVHD of the liver. The histologic features of hepatic GVHD are endothelialitis, lymphocytic infiltration of the portal areas, pericholangitis, and bile duct destruction and loss.

Other Organs

Whether GVHD affects organs other than the classic triad of skin, liver, and gut has remained a matter of debate, although numerous reports suggest additional organ manifestations. The most likely candidate is the lung. Lung toxicity, including interstitial pneumonitis and diffuse alveolar hemorrhage, may occur in 20% to 60% of allogeneic transplant recipients but in fewer autologous transplant recipients. Causes of pulmonary damage other than GVHD include engraftment syndrome (see earlier), infection, radiation pneumonitis, and chemotherapy-related toxicity (e.g., methotrexate, busulfan). One retrospective analysis failed to link severe pulmonary complications to clinical acute GVHD per se. The mortality due to pneumonia increases with the severity of GVHD, but this association may be related to increased immunosuppressive therapy.

Despite the ability of kidneys and hearts to serve as targets of transplant rejection, there is no convincing evidence for direct renal or cardiac damage from acute GVHD that is not secondary to drugs or infection. Similarly, neurologic complications are also common after transplantation but most can be attributed to drug toxicity, infection, or vascular insults.

Differential Diagnosis

Acute GVHD ought to be distinguished from any process that causes a constellation of fever, erythematous skin rash, and pulmonary edema that may occur during neutrophil recovery and has been termed engraftment or capillary leak syndrome. In allogeneic transplant recipients, distinction from acute GVHD is difficult. Engraftment syndrome is thought to reflect cellular and cytokine activities during early recovery of (donor-derived) blood cell counts and/or homeostatic proliferation of lymphocytes, but a precise delineation of the activated cells and mechanisms has not been demonstrated. Engraftment syndrome may be associated with increased mortality, primarily but not exclusively from pulmonary failure. Corticosteroid therapy may be effective particularly for the treatment of pulmonary manifestations. Skin rashes may reflect delayed reactions to the conditioning regimen, antibiotics, or infections; furthermore, histopathologic skin changes consistent with acute GVHD can be mimicked by chemoradiotherapy and drug reactions. Diarrhea can be a consequence of total body irradiation (TBI), viral infection (especially with cytomegalovirus [CMV] and other herpes viruses), parasitic infection, *Clostridioides difficile* infection, nonspecific gastritis, narcotic withdrawal, and drug reactions—all of which mimic GVHD of the gut. Liver dysfunction can be due to parenteral nutrition, VOD, and viral- or drug-induced hepatitis. Thus establishing a diagnosis of GVHD requires consideration of the timing of events in relation to HCT conditioning as well as exclusion of relevant infectious etiologies in HCT patients.

Genetic Basis of Graft-Versus-Host Disease

The graft-versus-host (GVH) reaction was first noted when irradiated mice were infused with allogeneic marrow and spleen cells. Although mice recovered from radiation-induced injury and marrow aplasia, they subsequently died with "secondary disease," a phenomenon subsequently recognized as acute GVHD. Three requirements for the development of GVHD were formulated by Billingham. First, the graft must contain immunologically competent cells, now recognized as mature T cells. In both experimental and clinical allogeneic HCT, the severity of GVHD correlates with the number of donor T cells transfused. The precise nature of these cells and the mechanisms they use are now understood in greater detail (see later). Second, the recipient must be incapable of rejecting the transplanted cells (i.e., immunocompromised). After allogeneic HCT, the recipient is typically immunosuppressed by chemotherapy and/or radiotherapy before the hematopoietic cell infusion. Third, the recipient must express tissue antigens that are not present in the transplant donor. Thus Billingham's third postulate stipulates that the GVH reaction occurs when donor immune cells recognize disparate host antigens. These differences are governed by the genetic polymorphisms.

Human Leukocyte Antigen Matching

Recognition of alloantigens depends on the match with the presenting major histocompatibility molecule. In humans, the MHC is governed by the HLA antigens that are encoded by the MHC gene complex on the short arm of chromosome 6 and can be categorized as class I, II, and III. Class I antigens (HLA-A, B, and C) are expressed on almost all cells of the body. Class II antigens (DR, DQ, and DP) are primarily expressed on hematopoietic cells, although their expression can also be induced on other cell types following inflammation. The incidence of acute GVHD is directly related to the degree of MHC mismatch. For example, recipients of single loci mismatched unrelated donors have higher rates of grade II to IV GVHD, higher transplant-related mortality, and inferior survival compared with 8/8 HLA-matched unrelated donors.[7,8] In the context of 8/8 HLA matching, mismatching that was nonpermissive (based on T-cell epitope grouping) was associated with increased mortality compared with permissive mismatches.[9] In alternative donor HCT the degree of HLA disparities also correlates with GVHD risk; however, there appears to be greater permissiveness as compared with unrelated donor transplant. However, it should be acknowledged that direct comparisons between various donor source are challenging because conditioning regimens and GVHD prevention platforms may differ significantly.

Minor Histocompatibility Antigens

In most clinical allogeneic transplants where the MHC of donor and recipient are matched, donor T cells recognize MHC-bound peptides derived from the protein products of polymorphic genes (MiHAs) that are present in the host but not in the donor. Substantial numbers (50%) of patients will develop acute GVHD despite receiving HLA-identical grafts as well as optimal postgrafting immune suppression. MiHAs are widely but variably expressed in different tissue, which is one possible explanation for the unique target organ distribution in GVHD. Many MiHAs such as HA-1 and HA-2 are expressed on hematopoietic cells, which may be one reason for the host immune system to be a primary target for the GVH response, and help to explain the critical role of direct presentation by professional recipient antigen-presenting cells (APCs) in the GVH response. By contrast, other MiHAs such as H-Y and HA-3 are expressed ubiquitously. MiHAs do not all equally induce lethal GVHD but show hierarchic immunodominance. Furthermore, the difference in a single immunodominant MiHA is insufficient to elicit GVHD in murine models, even though a single MiHA can elicit T cell–mediated damage in a skin explant model. However, the role of specific MiHAs that are able to induce clinical GVHD has not been systematically evaluated in large groups of patients.

Other Non-HLA Genes

Genetic polymorphisms in several non-HLA genes such as in killer-cell immunoglobulin (Ig)-like receptors (KIRs), cytokines, and nucleotide-binding oligomerization domain containing 2 *(NOD2)* genes have been shown to modulate the severity and incidence of GVHD.

KIRs on natural killer (NK) cells that bind to the HLA class I gene products are encoded on chromosome 19. Polymorphisms in the transmembrane and cytoplasmic domains of KIRs govern whether the receptor has inhibitory (e.g., KIR2DL1, -2DL2, -2DL3, and -3DL1) or activating potential. Two competing models have been proposed for HLA-KIR allorecognition by donor NK cells following allogeneic HCT: the “mismatched ligand” and the “missing ligand” models. Both models are supported by several clinical observations, albeit in patients receiving very different transplant and immunosuppressive regimens (see Chapters 21 and 107).

Proinflammatory cytokines involved in the classic cytokine storm of GVHD cause pathologic damage to target organs, such as the skin, liver, and GI tract (see later). Several cytokine gene polymorphisms in both recipients and donors have been implicated. Specifically, tumor necrosis factor (TNF) polymorphisms (TNFd3/d3 in the recipient, TNF863 and TNF857 in donors and/or recipients, and TNFd4, TNF-α-1031C, and TNFRII-196R in the donors) have been associated with an increased risk for acute GVHD and transplant-related mortality (TRM). The three common haplotypes of the interleukin (IL)-10 gene promoter region in recipients, representing high, intermediate, and low production of IL-10, have been associated with severity of acute GVHD following HLA-matched sibling donor allogeneic HCT. By contrast, smaller studies have found neither IL-10 nor TNF-α polymorphisms to be associated with GVHD following HLA-mismatched cord blood transplant (CBT). Interferon-γ (IFN-γ) polymorphisms of the 2/2 genotype (high IFN-γ production) and 3/3 genotype (low IFN-γ) have been associated with decreased or increased acute GVHD, respectively.

NOD2/caspase-activating recruitment domain 15 *(CARD15)* gene polymorphisms in both the donors and recipients were recently shown to have a striking association between GI GVHD and overall mortality following related and unrelated donor allogeneic HCT. It is likely that the importance of non-HLA gene polymorphisms in GVHD will differ depending on the donor source (related vs. unrelated), HLA disparity (matched vs. mismatched), graft source (cord blood vs. bone marrow vs. peripheral blood stem cells), and the intensity of the conditioning.

PATHOPHYSIOLOGY OF ACUTE GRAFT-VERSUS-HOST DISEASE

It is helpful to remember two important principles when considering the pathophysiology of acute GVHD. First, acute GVHD represents exaggerated but normal inflammatory responses against foreign antigens (alloantigens) that are ubiquitously expressed in a setting where they are undesirable. The donor lymphocytes that have been infused into the recipient function appropriately, given the foreign environment they encounter. Second, donor lymphocytes encounter tissues in the recipient that have been often profoundly damaged. The effects of the underlying disease, prior infections, and the intensity of conditioning regimen all result in substantial changes not only in the immune cells but also in the endothelial and epithelial cells. Thus the allogeneic donor cells rapidly encounter not simply a foreign environment, but one that has been altered to promote the activation and proliferation of inflammatory cells. Therefore the pathophysiology of acute GVHD may be considered a distortion of the normal inflammatory cellular responses that, in addition to the absolute requirement of donor T cells, involves multiple other innate and adaptive cells and mediators. The development and evolution of acute GVHD can be conceptualized in three sequential phases (Fig. 109.2) to provide a unified perspective on the complex cellular interactions and inflammatory cascades that lead to acute GVHD: (1) activation of the APCs; (2) donor T-cell activation, differentiation, and migration; and (3) effector phase. It is important to note that this three-phase description permits a unified perspective on GVHD biology, but it is not meant to suggest that all three phases are of equal importance or that GVHD occurs in a stepwise and sequential manner. The spatiotemporal relationships among these biologic processes, depending on the context, are likely to of vary, and their relevance to the induction, severity, and maintenance of GVHD may depend on the factors cited earlier.

Phase 1: Host Tissue Injury and Activation of Antigen-Presenting Cells

The earliest phase of acute GVHD is initiated by the profound damage caused by the underlying disease and infections and further exacerbated by BMT conditioning regimens (which include TBI and chemotherapy) that are administered even before the infusion of donor cells. This first step results in activation of the APCs. Specifically, secretion of proinflammatory cytokines from APCs, such as TNF-α and IL-1, described as the “cytokine storm.” More recently, HCT models have revealed an emerging role for damage-associated molecular patterns (DAMPs), released from injured host tissues, and pathogen-associated molecular patterns (PAMPs), from microbes, in amplifying inflammation and GVHD. These “danger signals” engage TLRs and other pattern recognition receptors to activate host APCs. Damage to the GI tract from the conditioning is particularly important in this process because it allows for systemic translocation of immunostimulatory PAMPs such as lipopolysaccharide (LPS) that further enhance the activation of host APCs, and the secondary lymphoid tissue in the GI tract is likely the initial site of interaction between activated APCs and donor T cells. This scenario accords with the observation that an increased risk for GVHD is

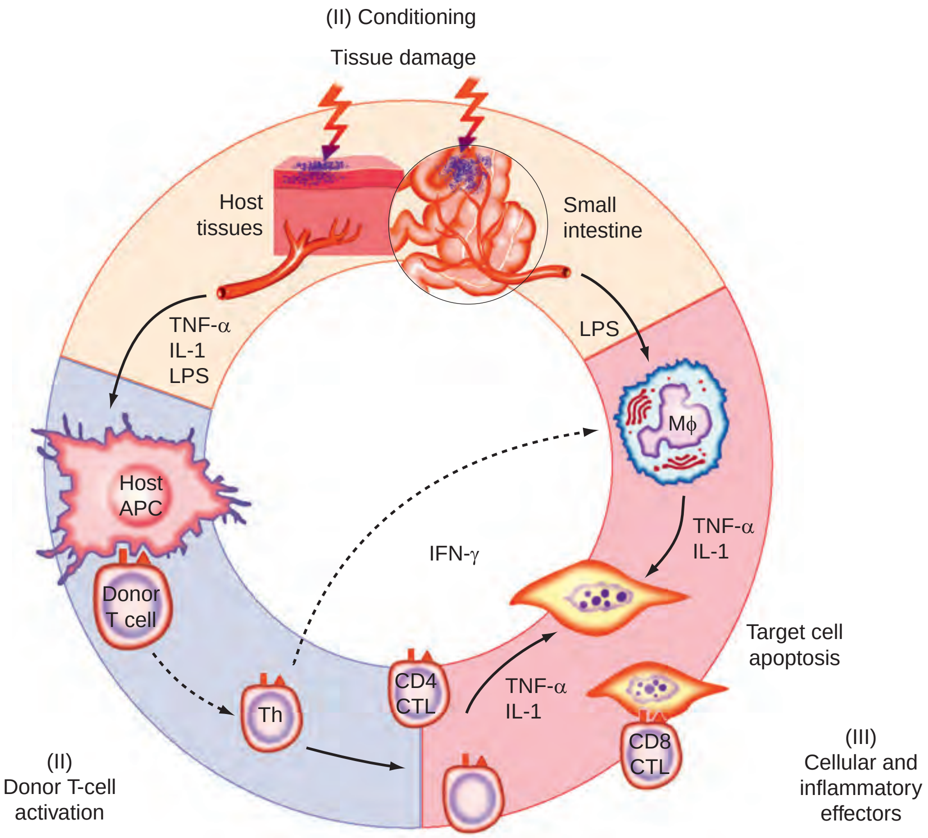

Figure 109.2 PATHOPHYSIOLOGY OF GRAFT-VERSUS-HOST DISEASE. During step 1, irradiation and chemotherapy both damage and activate host tissues, including intestinal mucosa, liver, and the skin. Activated cell hosts then secrete inflammatory cytokines (e.g., tumor necrosis factor [TNF]-α and interleukin [IL]-1), which can be measured in the systemic circulation. The cytokine release has important effects on antigen-presenting cells (APCs) of the host, including increased expression of adhesion molecules (e.g., intracellular adhesion molecule-1, vascular cell adhesion molecule-1) and of major histocompatibility (MHC) class II antigens. These changes in the APCs enhance the recognition of host MHC and/or minor H antigens by mature donor T cells. During step 2, donor T-cell activation is characterized by proliferation of GVHD T cells and secretion of the Th1 cytokines IL-2 and interferon (IFN)-γ. Both of these cytokines play central roles in clonal T-cell expansion, induction of cytotoxic T lymphocyte (CTL) and natural killer (NK) cell responses, and the priming of mononuclear phagocytes. In step 3, mononuclear phagocytes primed by IFN-γ are triggered by a second signal such as endotoxin (lipopolysaccharide [LPS]) to secrete cytopathic amounts of IL-I and TNF-α. LPS can leak through the intestinal mucosa damaged by the conditioning regimen to stimulate gut-associated lymphoid tissue or Kupffer cells in the liver; LPS that penetrates the epidermis may stimulate keratinocytes, dermal fibroblasts, and macrophages to produce similar cytokines in the skin. This mechanism results in the amplification of local tissue injury and further production of inflammatory effectors such as nitric oxide, which, together with CTL and NK effectors, leads to the observed target tissue destruction in the stem cell transplant host. CTL effectors use Fas/Fas ligand, perforin/granzyme B, and membrane-bound cytokines to lyse target cells.

associated with intensive conditioning regimens that cause extensive injury to epithelial and endothelial surfaces with a subsequent release of inflammatory cytokines and increases in expression of cell surface adhesion molecules. The relationship among conditioning intensity, inflammatory cytokine, and GVHD severity has been supported by elegant murine studies. Furthermore, the observations from these experimental studies have led to two recent clinical innovations to reduce clinical acute GVHD: (1) reduced intensity conditioning to decrease the damage to host tissues and thus limit activation of host APC and (2) KIR mismatches between donor and recipients to eliminate the host APCs by the alloreactive NK cells.

Host-type APCs that are present and have been primed by conditioning are critical for the induction of this phase; recent evidence suggests that donor-type APCs exacerbate GVHD, but in certain experimental models, donor-type APC chimeras also induce GVHD. In clinical situations, if donor-type APCs are present in sufficient quantity and have been appropriately primed, they too might play a role in the initiation and exacerbation of GVHD. Among the cells with antigen-presenting capability, dendritic cells (DCs) are the most potent and play an important role in the induction of GVHD. Experimental data suggest that GVHD can be regulated by qualitatively or quantitatively modulating distinct DC subsets. Langerhans cells were also shown to be sufficient for the induction of GVHD when all other APCs were unable to prime donor T cells, although the role for Langerhans cells when all APCs are intact is dispensable. Studies have yet to define roles for other DC subsets. In one clinical study, persistence of host DC after day 100 correlated with the severity of acute GVHD, whereas elimination of host DCs was associated with reduced severity of acute GVHD. The allostimulatory capacity of mature monocyte-derived DCs (mDCs) after reduced intensity transplants was lower for up to 6 months compared with the mDCs from myeloablative transplant recipients, thus suggesting a role for host DCs and the reduction in danger signals secondary to less intense conditioning in acute GVHD. Nonetheless this concept of enhanced host APC activation explains a number of clinical observations such as increased risks for acute GVHD associated with advanced-stage malignancy, conditioning intensity, and histories of viral infections.

Other professional APCs such as monocytes/macrophages or semiprofessional APCs might also play a role in this phase. For example, recent data suggest that host-type B cells might play a regulatory role under certain contexts, whereas in other contexts, they were dispensable for GVHD induction. Similarly, host basophils have been shown not to affect the induction or severity of acute GVHD. Recent data suggest that radiosensitive hematopoietic-derived APCs may not be obligatory for induction of APCs. In addition, host- or donor-type nonhematopoietic stem cells (e.g., mesenchymal stem cells, endothelial cells, epithelial cells, or stromal cells) can function as APCs in the context of inflammation. The role of these cells in the presence and absence of professional hematopoietic-derived APCs remains to be elucidated.

Host Tissue Injury and the Microbiome

GI tract cells such as intestinal epithelial cells (IECs), intestinal stem cells (ISCs), and Paneth cells are targeted in GI GVHD. GI tract damage from conditioning along with subsequent disruptions in intestinal homeostasis, which are further compounded by the use of broad-spectrum antibiotics and alterations in nutrition that occur during the process of allogeneic HCT, are now understood to play important roles in augmenting GVHD.

Maintenance of intestinal homeostasis is in part regulated by the intestinal microbiota and its interactions with the host immune system.[10] The host immune system has been shown to modulate the intestinal microbiota and its disturbances result in intestinal microbiota dysbiosis. For example, retinoic acid receptor–related orphan receptor-γt (RORγt)$^+$ group 3 innate lymphoid cells (ILC3s) regulate intestinal bacteria by limiting local and systemic inflammation, and the absence of intestinal immune cells, particularly isolated lymphoid follicles (ILFs), has been shown to result in alteration of the intestinal microbiota of mice by over representation of gram-negative bacteria. The intestinal microbiota also modulates host immune responses. Germ-free mice developed an increase in IFN-γ after colonization with *Escherichia coli*. In another study, germ-free mice colonized with conventional intestinal microbiota developed structural changes in the depth of the intestinal epithelial crypts as well as expansion in the lamina propria with an increase in immune cells after exposure to intestinal bacteria. Multiple studies have linked the intestinal microbiota to regulation of T cells. In one study, it was shown that colonization of mice with segmented filamentous bacteria (SFB) induces CD4$^+$ T helper cells in the lamina propria. In other studies, several intestinal microbes have been shown to induce forkhead box protein (Foxp3)-expressing regulatory T cells (Tregs). Furthermore, interactions between the intestinal microbiota and the host promote the functions of nonimmune cells such as IECs and goblet cells which play important roles in regulating the barrier function of the GI tract. Thus emerging data now strongly point to intestinal microbiota as playing an important role in intestinal homeostasis and augmenting GVHD.

Microbial Changes in Acute Graft-Versus-Host Disease

After allogeneic HCT there is loss of microbial diversity with a shift towards *Enterococci* and fewer obligate anaerobic bacteria, such as *Frimicutes*. This change can be pronounced with routine clinical use of antibiotics and the development of GVHD. Acute GVHD itself has been associated with major fluctuations in the intestinal microbiota, including a general loss of diversity and expansion of *Enterobacteriales* (including *Escherichia*, *Klebsiella*, and *Enterobacter*), *Lactobacillales* (including *Lactobacillus*, *Enterococcus*, and *Streptococcus*), *Proteobacteria*, and *Akkermansia*. This expansion is accompanied with loss of beneficial microbes including *Firmicutes* (including *Clostridia* and *Blautia*).[11] Accompanying these shifts is Paneth cell loss in experimental GVHD that results in decreased secretion of α-defensins, leading to further intestinal dysbiosis, and that loss of Paneth cells and dysbiosis were associated with nonrelapse mortality (NRM) in clinical GVHD.[12] Several studies have noted that expansion of specific pathogenic bacteria (VRE, *Enterococcus*) often preceded bloodstream infections by the same organisms and identified treatment with certain antibiotics with anaerobic coverage such as metronidazole as a risk factors for bacterial expansion. The intestinal microbiota can also modulate acute GVHD severity. In the 1970s, investigators paradoxically found less GVHD in mice transplanted in germ-free conditions or receiving gut decontamination antibiotics. These studies have not been confirmed in modern day germ-free mice facilities. However, early clinical studies also showed similar beneficial effects of bacterial decontamination in allogeneic HCT patients, although subsequent studies did not replicate these benefits. More recent research made major strides in investigating the specific alterations in the composition of the intestinal microbiota and their association with acute GVHD. In one study, high intestinal abundance of the anaerobic bacteria *Blautia* was correlated with lower rates of GVHD and improved survival. Loss of diversity of the intestinal microbiota was associated with increased mortality in allogeneic HCT patients which was attributed to increased death due to GVHD or infection rather than relapse. Another study showed associations between the expansion of certain bacteria *Lactobacillales* as well as general loss of diversity and acute GVHD severity. This study also showed that expansion of Lactobacillales was not the cause for the development of GVHD because eliminating Lactobacillales from the intestinal flora in mice before allogeneic HCT caused more severe GVHD and reintroducing Lactobacillales alleviated this effect. However, another study found that that modifying the intestinal microbiota using the probiotic microorganism *Lactobacillus rhamnosus GG* reduced experimental GVHD. Similarly, administration of a cocktail of 17 species of *Clostridia* reduced experimental GVHD and improved survival.[13] These data suggest that probiotic therapy might become a rational strategy for ameliorating GVHD. As such, limited published early clinical experiences explored the use of probiotics, including via fecal microbiota transplantation (FMT) in allogeneic HCT patients. However, such approaches require rigorous assessments of safety in immunocompromised populations, as well as challenges related to scalability for widespread application in large prospective trials.

Use of Antibiotics

A recent retrospective study showed that broad-spectrum antibiotic treatment with imipenem-cilastatin and piperacillin-tazobactam was associated with increased GVHD-related mortality in patients and that treatment with imipenem-cilastatin was associated with loss of the protective mucus lining of the colon and a shift toward *Akkermansia* in mice. Antibiotic agents with more limited spectra of activity such as rifaximin, cefepime, and aztreonam were associated with reduced GVHD severity. The use of rifaximin correlated with a lower enterococcal load after allogeneic HCT and the use of cefepime and aztreonam correlated with less alterations to the composition of the intestinal microbiota post allogeneic HCT when compared with broader-spectrum antibiotics with increased anaerobic activity.

Microbial Metabolites in Acute Graft-Versus-Host Disease

The intestinal microbiota metabolize nutrients ingested by the host and produce microbial metabolites which play critical roles in the microbiota's interactions with the host and in maintaining intestinal homeostasis. Microbial metabolites include essential fatty acids and amino acids for the host. Short-chain fatty acids (SCFAs) are the most studied microbial metabolites. Examples of other microbial metabolites are bile acids, polyamines, and aryl hydrocarbon receptor (AhR) ligands. These metabolites impact both nonimmune and immune intestinal cells as well as the microbiome and have varying functions in maintaining the barrier surface of the GI tract, as well as modulating the innate and adaptive host immune responses.

Short-Chain Fatty Acids

SCFAs (e.g., butyrate, proprionate, and acetate) are produced from fermentation of indigestible carbohydrates by intestinal anaerobic commensal bacteria such as *Clostridia* species and impact both nonimmune and immune intestinal cells. SCFAs serve as an energy source for the intestinal microbiota and IECs and assist in maintaining the integrity of the mucosal barrier. For example, goblet cells upregulated their expression of mucin genes in response to SCFAs and inoculating germ-free rats with SCFA-producing *Bacteroides thetaiotaomicron* or *Faecalibacterium prausnitzii* induced goblet cell differentiation and mucus production. Furthermore, colonization with *Bifidobacterium longum* protected mice against death induced by a lethal infection by increasing production of SCFA acetate, which maintained the barrier integrity of IECs and inhibited translocation of the *E. coli* O157:H7 Shiga toxin from the gut lumen into the blood. Finally, SCFAs play an important part in innate immunity because they are histone deacetylase (HDAC) inhibitors with antiinflammatory effects. These observations reveal a crucial protective function of the microbiome in regulating the response of host tissues to immunologic and/or cytotoxic insults that occur after HCT.

Dietary Resistant Starch and Short-Chain Fatty Acids

One potential approach for stimulating SCFA production could be via dietary supplementation with carbohydrates that are resistant to degradation by human enzymes but can be metabolized by select microbes in the gut. Multiple studies have reported increased fecal SCFAs, particularly butyrate, by dietary supplementation with different formulations of resistant starch (RS). Another study showed that one such RS prepared from potatoes (RPS) is more potent at increasing average fecal butyrate levels compared with other RS formulations. Butyrate production from RS is a complex multistep process, and understanding all the gut microbes involved in this process is an ongoing challenge. Only a limited number of gut bacteria can degrade RS; however, most primary RS degraders are not among the known butyrate producers. Thus, for dietary supplementation with RS to stimulate butyrate production, the activities of secondary fermenters are required. These secondary fermenters capture degradation and fermentation products from primary degraders and metabolize them into new molecules, including butyrate. Known primary RS degraders include *Ruminococcus bromii*, *Ruminococcus lactaris*, *Ruminococcus gnavus*, and *Bifidobacterium* spp., and known butyrate producers (secondary fermenters) include *Roseburia* spp., *F. prausnitzii*, *Eubacterium rectale*, and *Anaerostipes* spp.

Short-Chain Fatty Acids and Acute Graft-Versus-Host Disease

A recent murine study explored the role of microbial metabolites, specifically SCFAs, in acute GVHD severity and found that the SCFA butyrate was significantly decreased in the IECs of mice experiencing acute GVHD.[13] Restoring butyrate levels, either by direct administration of butyrate or by increasing intestinal butyrate-producing bacteria, reduced acute GVHD. Two SCFAs, butyrate and propionate, were shown to directly protect IECs and reduce acute GVHD severity in mice. A small clinical study found that fecal butyrate and propionate levels are decreased in patients after allogeneic HCT and are lower with antianaerobic antibiotic exposure. Another recent clinical study examined fecal SCFA concentrations after allogeneic HCT and found that higher levels of butyrate and other SCFAs correlated with abundance of butyrate-producing organisms in the intestinal microbiota and this abundance was associated with resistance against lower tract respiratory infections. However, the impact of SCFA levels on acute GVHD has yet to be examined in patients post allogeneic HCT.

Dietary Manipulation of the Microbiome-Metabolome Axis and Acute Graft-Versus-Host Disease

Diet affects the composition of the intestinal microbiome and the associated metabolome is correspondingly altered. In one study, high-protein and low-carbohydrate diet was associated with loss of members of *Clostridiales*, including *Roseburia*, *Faecalibacterium*, *Ruminococcus*, and *Blautia*. Similar patterns were seen with diets derived entirely from animal products. Turnbaugh et al. showed that changes in diet from a low-fat, plant polysaccharide–rich diet to a high-fat, high-sugar diet in mice that were colonized with human feces altered the intestinal microbiota composition and this was accompanied by changes in the metabolic milieu. In two other studies, researchers showed that total parenteral nutrition resulted in a proinflammatory pattern of immune responses in mice and humans. These data suggest that diet can alter the intestinal microbiota and the metabolome and thereby regulate intestinal homeostasis.

Specific elements of the diet called prebiotics, which usually refer to indigestible carbohydrates that are metabolized by the intestinal microbiota to produce SCFAs, are particularly influential in modulating the structure and function of the intestinal microbiota. Despite their wide commercial availability, here is lack of published clinical data on the effect of prebiotics in acute GVHD. However, several studies showed that the prebiotics inulin and fructo-oligosaccharides increased intestinal microbiota diversity and decreased disease activity in inflammatory bowel disease patients. These studies, along with the evidence that SCFAs protect IECs and reduce experimental acute GVHD severity, provide a compelling rationale for now ongoing studies of dietary manipulation of the microbiome-metabolome axis using prebiotics to mitigate acute GVHD in patients receiving allogeneic HCT.

Phase 2: Donor T-Cell Activation, Differentiation, and Migration

The infused donor T cells interact with the primed APCs, leading to the initiation of the second phase of acute GVHD. This phase includes antigen presentation by primed APCs and the subsequent activation, proliferation, differentiation, and migration of alloreactive donor T cells. After allogeneic HSC transplants, both host- and donor-derived APCs are present in secondary lymphoid organs. The T-cell receptor (TCR) of the donor T cells can recognize alloantigens either on host APCs (direct presentation) or donor APCs (indirect presentation). In direct presentation, donor T cells recognize either the peptide bound to allogeneic MHC molecules or allogeneic MHC molecules without peptide. During indirect presentation, T cells respond to the peptide generated by degradation of the allogeneic MHC molecules presented on self-MHC. Experimental studies demonstrated that APCs derived from the host, rather than from the donor, are critical in inducing GVHD across MiHA mismatch. Recent data suggest that presentation of distinct target antigens by the host- and donor-type APCs might play a differential role in mediating target organ damage. In humans, most cases of acute GVHD developed when both host DCs and donor DCs were present in peripheral blood after BMT.

Costimulation

The interaction of donor lymphocyte TCR with the host allopeptide presented on the MHC of APCs alone is insufficient to induce T-cell activation. Both TCR ligation and costimulation via a “second” signal through interaction between the T-cell costimulatory molecules and their ligands on APCs are required to achieve T-cell proliferation, differentiation, and survival. The danger signals generated in phase 1 augment these interactions, and significant progress has been made on the nature and impact of these second signals. Costimulatory pathways are now known to deliver both positive and negative signals, and molecules from two major families, the B7 family and the TNF receptor (TNFR) family, play pivotal roles in GVHD. Interruption of the second signal by blockade of various positive costimulatory molecules (CD28, ICOS, CD40, CD30, 4-1BB, and OX40) reduces acute GVHD in several murine models, whereas antagonism of the inhibitory signals (PD-1 and CTLA-4) exacerbates the severity of acute GVHD. Blockade of activating costimulatory signals with the CTLA-4 fusion protein Abatacept has shown initial evidence of efficacy for prevention of GVHD in phase II clinical trials, particularly in settings of mismatched HCT.[14] Various T-cell and APC costimulatory molecules and the impact on acute GVHD are summarized in Table 109.3. The specific context and the hierarchy in which each of these signals plays a dominant role in the modulation of GVHD remain to be determined.

T-Cell Subsets

T cells consist of several subsets whose responses differ based on antigenic stimuli, activation thresholds, and effector functions. The alloantigen composition of the host determines which donor T-cell subsets proliferate and differentiate.

TABLE 109.3 **T Cell–Antigen-Presenting Cell Interactions**

T Cell	APC
Adhesion	
ICAMs	LFA-1
LFA-1	ICAMs
CD2 (LFA-2)	LFA-3
Recognition	
TCR/CD4	MHC II
TCR/CD8	MHC I
Costimulation	
CD28	CD80/86
CD152 (CTLA-4)	CD80/86
ICOS	B7H/B7RP-1
PD-1	PD-L1, PD-L2
Unknown	B7-H3
CD154 (CD40L)	CD40
CD134 (OX 40)	CD134L (OX40L)
CD137 (4-1BB)	CD137L (4-1BBL)
HVEM	LIGHT

APC, Antigen-presenting cell; *HVEM*, HSV glycoprotein D for herpesvirus entry mediator; *LIGHT*, homologous to lymphotoxins, shows inducible expression, and competes with HVEM, a receptor expressed by T lymphocytes; *MHC*, major histocompatibility complex; *TCR*, T-cell receptor.

CD4$^+$ and CD8$^+$ *Cells*

CD4 and CD8 proteins are coreceptors for constant portions of MHC class II and class I molecules, respectively. Therefore MHC class I (HLA-A, -B, -C) differences stimulate CD8$^+$ T cells, and MHC class II (HLA-DR -DP, -DQ) differences stimulate CD4$^+$ T cells. However, clinical trials of CD4$^+$ or CD8$^+$ depletion have been inconclusive. Perhaps this is not surprising, because in the majority of HLA-identical BMT, GVHD is induced by MiHAs, which are peptides derived from polymorphic cellular proteins that are presented by MHC molecules. Because the manner of protein processing depends on genes of the MHC, two siblings will have many different peptides in the MHC groove. Thus, in the majority of HLA-identical BMT, acute GVHD can be induced by either or both CD4$^+$ and CD8$^+$ subsets in response to MiHAs. The peptide repertoire for class I or class II MHC remains unknown and might even be unique in different individuals. However, it is plausible that only a few of the many of these peptides might behave as immunodominant “major minor” antigens that can potentially induce GVHD. In any event, such antigens remain to be identified and validated in large patient population.

Naïve and Memory Subsets

Intriguingly, several independent groups have found that, although the naïve (CD62L$^+$) T cells were alloreactive and caused acute GVHD, this was not the case for the memory (CD62L$^-$) T cells across different donor/recipient strain combinations. Furthermore, expression of naïve T-cell marker CD62L was also found to be critical for regulation of GVHD by donor natural Tregs. By contrast, another recent study demonstrated that alloreactive memory T cells and their precursor cells (memory stem cells) caused robust GVHD. It remains as yet unknown whether the reduced GVHD potential of memory-type T cells from a naïve murine donor, in contrast to their ability to cause greater solid organ allorejection, is a consequence of the intense conditioning regimen and/or altered trafficking or from a restricted repertoire and/or T-cell intrinsic defect.

Regulatory T Cells

Recent advances indicate that distinct subsets of regulatory CD4$^+$CD25$^+$, CD4$^+$CD25$^-$IL10$^+$ T responder (Tr) cells, γδT cells, double negative (DN$^-$) T cells, NK T cells, and regulatory DCs control immune responses by induction of anergy or active suppression of alloreactive T cells. Several studies have demonstrated a critical role for the natural donor CD4$^+$CD25$^+$ Foxp3$^+$ Tregs, obtained from naïve animals or generated ex vivo, in the outcome of acute GVHD. Donor CD4$^+$CD25$^+$T cells suppressed the early expansion of alloreactive donor T cells and their capacity to induce acute GVHD without abrogating GVL effector function against these tumors. CD4$^+$CD25$^+$ T cells induced and/or generated by of immature or regulatory host-type DCs and by regulatory donor-type myeloid APCs were also able to suppress acute GVHD. One of the clinical studies that evaluated the relationship between donor CD4$^+$CD25$^+$ cells and acute GVHD in humans after matched sibling donor grafts found that in contrast to the murine studies, donor grafts containing larger numbers of CD4$^+$CD25$^+$T cells developed more severe acute GVHD. These data suggest that coexpression of CD4$^+$ and CD25$^+$ is insufficient because an increase in CD25$^+$ T cells in donor grafts is associated with greater risks for acute GVHD after clinical HCT. Another recent study found that Foxp3 mRNA expression (considered a specific marker for naturally occurring CD4$^+$CD25$^+$Tregs) was significantly decreased in peripheral blood mononuclear cells from patients with acute GVHD, but Foxp3 expression in humans, unlike mice, may not be specific for T cells with a regulatory phenotype. It is likely that the precise role of Tregs in clinical acute GVHD will therefore depend not only on identification of specific molecular markers in addition to Foxp3 but also on the ability for ex vivo expansion of these cells in sufficient numbers. The presence of STAT1 signaling has been shown to enhance Treg-mediated suppression of GVHD. Recent observations have demonstrated key roles for host APCs in the induction and for donor APCs in the sustenance of infused mature Tregs. Several early-phase clinical trials have been conducted in the United States and Europe using various methods to expand these cells ex vivo and use for prevention of GVHD. Emerging data from these trials suggest that donor Tregs can reduce incidence of clinical GVHD and do not prevent engraftment.[15]

Host NK1.1$^+$ T cells are another T-cell subset that has been shown to suppress acute GVHD in an IL-4 dependent manner. By contrast, donor NKT cells were found to reduce GVHD and enhance perforin-mediated GVL in an IFN-γ–dependent manner. Clinical data suggest that enhancing recipient NKT cells by repeated total lymphoid irradiation (TLI) conditioning promoted T-helper 2 (Th2) polarization and dramatically reduced GVHD. Experimental data also show that activated donor NK cells can reduce GVHD through the elimination of host APCs or by secretion of transforming growth factor-β (TGF-β) secretion. A BMT study using mice lacking SH2-containing inositol phosphatase (SHIP), in which the NK compartment is dominated by cells that express two inhibitory receptors capable of binding either self or allogeneic MHC ligands, suggests that host NK cells may play a role in the initiation of GVHD.

T-Cell Apoptosis

Deletional mechanisms of tolerance fall into two categories: (1) central (thymic) deletion and (2) peripheral deletion. Central deletion is an effective way to eliminate continued thymic production of alloreactive T cells. To this end, lymphoablative treatments have been used as a condition to create a mixed hematopoietic chimeric state in murine BMT models. In this strategy, donor cells seed the thymus and maturing donor-reactive T-cell clones are deleted through intrathymic apoptosis. The proportion of the peripheral T-cell repertoire that can respond to allogeneic MHC antigens may play a critical role in the development of tolerance. In the case of MHC-mismatched transplantation, the frequency of alloreactive T cells is at least five orders of magnitude greater than the frequency of peptide-specific T cells responding to a nominal antigen. The pathways of T-cell apoptosis by which peripheral deletion occurs can be broadly categorized into activation-induced cell death (AICD) and passive cell death (PCD). An important mediator of AICD in T cells is the Fas receptor. Activated T cells expressing the Fas molecule undergo apoptotic cell death when brought into contact with cells expressing Fas ligand (FasL). A critical role for Fas-mediated AICD has been clearly demonstrated in attenuation of acute GVHD by several Th1 cytokines.

PCD, or "death by neglect," illustrates the exquisite dependence of activated T cells on growth factors (e.g., IL-2, IL-4, IL-7, and/or IL-15) for survival; apoptotic cell death in this instance is largely due to rapid downregulation of BCL2. Transplantation of BCL-XL T cells into nonirradiated recipients significantly exacerbates GVHD; however, no difference in GVHD mortality is observed in animals that have been lethally irradiated. Selective elimination of donor T cells in vivo after BMT using transgenic T cells in which a thymidine kinase (TK) suicide gene is targeted to T cells has also been shown to attenuate the severity of acute GVHD. Another recent approach to prevent GVHD is the selective depletion of alloantigen-specific donor T cells by photodynamic cell purging process, wherein donor T cells are treated with photoactive 4,5-dibromorhodamine 123 and subsequently exposed to visible light. Thus several deletional mechanisms have been shown to reduce acute GVHD, but the conditions under which one or another of these deletional mechanisms predominates role remain to be determined.

Cytokines and T-Cell Differentiation

APC and T-cell activation results in rapid intracellular biochemical cascades that induce the transcription of many genes, including cytokines and their receptors. The Th1 cytokines (IFN-γ, IL-2, and TNF-α) have been implicated in the pathophysiology of acute GVHD. IL-2 production by donor T cells remains the main target of many current clinical therapeutic and prophylactic approaches, such as CSP, tacrolimus, and monoclonal antibodies (mAbs) against the IL-2 and its receptor to control acute GVHD. However, emerging data indicate an important role for IL-2 in the generation and maintenance of CD4$^+$CD25$^+$ Foxp3$^+$ Tregs, suggesting that prolonged interference with IL-2 may have an unintended consequence in the prevention of the development of long-term tolerance after allogeneic HCT. Similarly, the role of other Th1 cytokines, IFN-γ, or their inducers as regulators or inducers of GVHD severity depends on the degree of allomismatch, the intensity of conditioning, and the T-cell subsets that are involved after BMT. Thus, although the cytokine storm initiated in phase 1 and amplified by the Th1 cytokines correlates with the development of acute GVHD, early Th1 polarization of donor T cells to HCT recipients can attenuate acute GVHD, suggesting that physiologic and adequate amounts of Th1 cytokines are critical for GVHD induction, whereas inadequate production (extremely low or high) could modulate acute GVHD through a breakdown of negative feedback mechanisms for activated donor T cells. Several different cytokines that polarize donor T cells to Th2 such as IL-4, granulocyte colony-stimulating factor (G-CSF), IL-18, IL-11, rapamycin, and the secretion of IL-4 by NK1.1$^+$ T cells can reduce acute GVHD. However, Th1 and Th2 subsets cause injury of distinct acute GVHD target tissues, and some studies failed to show a beneficial effect of Th2 polarization on acute GVHD. Thus the Th1/Th2 paradigm of donor T cells in the immunopathogenesis of acute GVHD has evolved over the past few years, and its causal role in acute GVHD is complex and incompletely understood.

IL-10 plays a key role in suppression of immune responses, and its role in regulating experimental acute GVHD is unclear. Recent clinical data demonstrate an unequivocal association of IL-10 polymorphisms with the severity of acute GVHD. TGF-β, another suppressive cytokine, was shown to suppress acute GVHD but to exacerbate chronic GVHD. The roles of some other cytokines, such as IL-7 (which promotes immune reconstitution) and IL-13 remain unclear. The role of IL-17–producing CD4$^+$ T cells (Th17) in GVHD is also unclear at present. Initial studies showed that donor T cells deficient in IL-17A augmented Th1 differentiation and exacerbated acute GVHD. In contrast, another study using a similar model showed that IL-17 contributed to CD4$^+$-mediated GVHD without affecting overall survival rates. In addition, the differentiation of Th17 cells in vitro appeared to cause lethal acute GVHD with severe cutaneous and pulmonary damage. More recently, IL-21, which is known to enhance Th17 cell differentiation while inhibiting the conversion of inducible Tregs from naïve T cells, has been shown to increase GVHD-induced injury. Consistent with this finding, the abrogation of IL-21 signaling in donor T cells has led to reduced GVHD mortality, which is associated with donor Treg expansion and decreased TNF-α. These conflicting results may be due to variations among the model systems, and further analyses are required to define the role of Th17 cells in GVHD.

CD4$^+$ and CD8$^+$ *T Cells*

As mentioned previously, in the majority of HLA-matched allogeneic HCTs, acute GVHD may be induced by either or both CD4$^+$ and CD8$^+$ subsets responses to MiHAs. The repertoire and immunodominance of the GVHD-associated peptides presented by MHC class I and class II molecules have not been clearly defined. One approach to retaining the beneficial GVL effects while eliminating the negative effects of GVHD is to selectively deplete subsets of donor alloreactive T cells in the hematopoietic cell inoculums using a TCR Vβ repertoire analysis with CDR3-size spectratyping.

Naïve and Memory T Cells

T cells in murine models can be categorized into naïve (CD62L$^+$ CD44$^-$), central memory (CD62L$^+$ CD44$^+$), and terminally differentiated effector/effector memory (CD62L$^-$ CD44$^-$) subsets. Donor naïve CD62L$^+$ T cells are the primary alloreactive T cells that drive the GVHD reaction, whereas the donor effector memory CD62L$^-$ T cells do not. Shedding of CD62L by antigen encountered T cells facilitates their egress from peripheral lymph tissues to the circulation, where they participate in helper and effector functions. Of interest, donor Treg cells expressing CD62L are critical to the regulation of GVHD. Specifically, it has been shown that CD62L^{hi} Tregs attenuate GVHD and promote allogeneic BM engraftment. The expression of CD62L is important for the migration of Tregs to secondary lymphoid organs, thereby inhibiting the initial expansion of donor T cells. We now know that it is possible to modulate the alloreactivity of naïve T cells by inducing anergy with costimulation blockade, deletion via cytokine modulation, or mixed chimerism. Donor effector memory T cells that are nonalloreactive do not induce GVHD yet are able to transfer functional memory and mediate GVL. In addition, lymphopenia-induced proliferation gives rise to cells that are like memory T cells and enhance the GVL effect after donor leukocyte infusion (DLI). As proof-of-concept, clinical studies of donor grafts depleted of CD34$^+$ cells and CD45RA$^+$ naïve T cells, with add-back of memory T cells have reported low rates of severe (corticosteroid-resistant) GVHD and chronic GVHD.[16] In contrast, memory T cells that are alloreactive can cause severe GVHD. However, more recently, Anderson and colleagues demonstrated that enhancing the alloreactivity of effector memory T cells can cause GVHD, although a less severe and possibly more transient GVHD in nature. These findings may be better understood with further analyses that would enable tracking of alloantigen-specific T cells (naïve, central memory, and effector memory subsets) in experimental GVHD and GVL models with defined TCR repertoires.

Leukocyte Migration

Donor T cells migrate to lymphoid tissues, recognize alloantigens on either host or donor APCs, and become activated. They then exit the lymphoid tissues, traffic to the target organs, and cause tissue damage. The molecular interactions necessary for T-cell migration and the role of lymphoid organs during acute GVHD have recently become the focus of a growing body of research. Chemokines play a critical role in the migration of immune cells to secondary lymphoid organs and target tissues. T-lymphocyte production of macrophage inflammatory protein-1α (MIP-1α) is critical to the recruitment of CD8$^+$ but not CD4$^+$ T cells to the liver, lung, and spleen during acute GVHD. Several chemokines such as CCL2–5, CXCL2, CXCL9–11, CCL17, and CCL27 are overexpressed and might play a critical role in the migration of leukocyte subsets to target organs liver, spleen, skin, and lungs during acute GVHD. CXCR3$^+$ and CCR5$^+$ T cells cause acute GVHD in the liver and intestine. CCR5 expression has also been found to be critical for Treg migration in GVHD. In addition to chemokines and their receptors, expression of selectins and integrins and their ligands also regulate the migration of inflammatory cells to target organs. For example, interaction between α4β7 integrin and its ligand MadCAM-1 are important for homing of donor T cells to Peyer patches and in the initiation of intestinal GVHD. αLβ2 intracellular adhesion molecule-1,2,3 (ICAM1,2,3) and α4β1/vascular cell adhesion molecule-2 (VCAM-2) interactions are important for homing to the lung and liver after experimental HCT. The expression of CD62L on donor Tregs is critical for their regulation of acute GVHD, suggesting that their migration in secondary tissues is critical for their regulatory effects. The migratory requirement of donor T cells to specific lymph nodes (e.g., Peyer patches) for the induction of GVHD might depend on other factors such as the conditioning regimen, inflammatory milieu, etc. Furthermore, FTY720, a pharmacologic sphingosine-1-phosphate receptor agonist, inhibited GVHD in murine but not in canine models of HCT. Thus significant species differences may also factor in the ability of these molecules to regulate GVHD.

Phase 3: Effector Phase

The effector phase that leads to the GVHD target organ damage is a complex cascade of multiple cellular and inflammatory effectors that further modulate each other's responses either simultaneously or successively. Effector mechanisms of acute GVHD can be grouped into cellular and inflammatory effectors. Inflammatory chemokines expressed in inflamed tissues upon stimulation by proinflammatory effectors, such as cytokines, are specialized for the recruitment of effector cells, such as cytotoxic T lymphocytes (CTLs). Furthermore, the spatiotemporal expression of the cytochemokine gradients might determine not only the severity but also the unusual cluster of GVHD target organs (skin, gut, and liver).

Cellular Effectors

CTLs are the major cellular effectors of GVHD. The principal CTL effector pathways that have been evaluated after allogeneic BMT are the Fas-FasL, the perforin-granzyme (or granule exocytosis), and the TNFR-like death receptors (DRs), such as TNF-related apoptosis-inducing ligand (TRAIL: DR4, 5 ligand), and TNF-like weak inducers of apoptosis (TWEAK: DR3 ligand). The involvement of each of these molecules in GVHD has been tested by using donor cells that are unable to mediate each pathway. Perforin is stored in cytotoxic granules of CTLs and NK cells, together with granzymes and other proteins. Although the exact mechanisms remain unclear, following the recognition of a target cell through the TCR-MHC interaction, perforin is secreted and inserted into the cell membrane, forming "perforin pores" that allow granzymes to enter the target cells and induce apoptosis through various downstream effector pathways such as caspases. Ligation of Fas results in the formation of the death-inducing signaling complex (DISC) and also activates caspases.

Transplantation of perforin-deficient T cells results in a marked delay in the onset of GVHD in transplants across MiHA disparities only, both MHC and MiHA disparities, and across isolated MHC I or II disparities. However, mortality and clinical and histologic signs of GVHD were still induced even in the absence of perforin-dependent killing in these studies, demonstrating that the perforin-granzyme pathway plays little role in target organ damage. A role for the perforin-granzyme pathway for GVHD induction is also evident in studies using donor T-cell subsets. Perforin- or granzyme B-deficient CD8$^+$ T cells caused less mortality than wild-type T cells in experimental transplants across a single MHC class I mismatch. However, this pathway seems to be less important compared with Fas/FasL pathway in CD4-mediated GVHD. Thus it seems that CD4$^+$ CTLs preferentially use the Fas-FasL pathway, whereas CD8$^+$ CTLs primarily use the perforin-granzyme pathway.

Fas, a TNF-receptor family member, is expressed by many tissues, including GVHD target organs. Its expression can be upregulated by inflammatory cytokines such as IFN-γ and TNF-α during GVHD, and the expression of FasL is also increased on donor T cells, indicating that FasL-mediated cytotoxicity may be a particularly important effector pathway in GVHD. FasL-defective T cells cause less GVHD in the liver, skin, and lymphoid organs. The Fas-FasL pathway is particularly important in hepatic GVHD, consistent with the keen sensitivity of hepatocytes to Fas-mediated cytotoxicity in experimental models of murine hepatitis. Fas-deficient recipients are protected from hepatic GVHD but not from other organ GVHD, and administration of anti-FasL (but not anti-TNF) mAbs significantly blocked hepatic GVHD damage occurring in murine models. Although the use of FasL-deficient donor T cells or the administration of neutralizing FasL MAbs had no effect on the development of intestinal GVHD in several studies, the Fas-FasL pathway may play a role in this target organ, because intestinal epithelial lymphocytes exhibit increased FasL-mediated killing potential. Elevated serum levels of soluble FasL and Fas have also been observed in at least some patients with acute GVHD.

The use of a perforin-granzyme and FasL cytotoxic double-deficient (cdd) mouse provides an opportunity to address whether other effector pathways are capable of inducing GVHD target organ pathology. An initial study demonstrated that cdd T cells were unable to induce lethal GVHD across MHC class I and class II disparities after sublethal irradiation. However, subsequent studies demonstrated that cytotoxic effector mechanisms of donor T cells are critical in preventing host resistance to GVHD. Thus, when recipients were conditioned with lethal dose of irradiation, cdd CD4$^+$ T cells produced similar mortality to wild-type CD4$^+$ T cells. These results were confirmed by a recent study demonstrating that GVHD target damage can occur in mice that lack alloantigen expression on the epithelium, preventing direct interaction between CTLs and target cells.

The participation of another death ligand receptor signaling pathway, TNF/TNFRs, has also been evaluated. Experimental data suggest that this pathway is crucial for GI GVHD (discussed in more detail later). Recently, several additional TNF family apoptosis-inducing receptors/ligands have been identified, including TWEAK, TRAIL, and LTβ/LIGHT, all of which have been proposed to play a role in GVHD and GVL responses. However, whether these distinct pathways play a more specific role for GVHD mediated by distinct T-cell subsets in certain situations remains unknown. Intriguingly, recent data suggest that none of these pathways might be critical for mediating the rejection of donor grafts. Thus it is likely that their role in GVHD might be modulated by the intensity of conditioning and by the recipient T-cell subsets. Existing experimental data suggest that perforin and TRAIL cytotoxic pathways are associated with CD8$^+$ T cell–mediated GVL. The available experimental data are strongly skewed toward CD8$^+$ T cell–mediated GVL, based on the dominant role of this effector population in most murine GVT models; however, CD4$^+$ T cells can mediate GVL and might be crucial in clinical BMT, depending on the type of malignancy and the expression of immunodominant antigens.

Taken together, experimental data suggest some distinction between the use of different lytic pathways for the specific GVHD target organs and GVL, but the clinical applicability of these observations is as yet largely unknown.

Inflammatory Effectors

Inflammatory cytokines synergize with CTLs, resulting in the amplification of local tissue injury and further promotion of an inflammation, which ultimately leads to the observed target tissue destruction in the transplant recipient. Macrophages, which had been primed with IFN-γ during step 2, produce inflammatory cytokines TNF-α and IL-1 when stimulated by a secondary triggering signal. This stimulus may be provided through Toll-like receptors (TLRs) by microbial products such as LPS and other microbial particles, which can leak through the intestinal mucosa damaged by the conditioning regimen and gut GVHD. It is now apparent that immune recognition through both TLR and non-TLRs (e.g., NOD) by the innate immune system also controls activation of adaptive immune responses. Recent clinical studies of GVHD suggested the possible association with TLR/NOD polymorphisms and severity of GVHD. LPS and other immunogenic stimuli such as DAMPs may stimulate gut-associated lymphocytes, keratinocytes, dermal fibroblasts, and macrophages to produce proinflammatory effectors that play a direct role in causing target organ damage. Indeed, experimental data with MHC mismatched BMT suggest that under certain circumstances these inflammatory mediators are sufficient in causing GVHD damage even in the absence of direct CTL-induced damage. The severity of GVHD appears to be directly related to the level of innate and adaptive immune cell priming and release of proinflammatory cytokines such as TNF-α, IL-1, and nitric oxide (NO).

The cytokines TNF-α and IL-1 are produced by an abundance of cell types during processes of both innate and adaptive immunity; they often have synergistic, pleiotropic, and redundant effects on both activation and effector phases of GVHD. A critical role for TNF-α in the pathophysiology of acute GVHD was first suggested more than 20 years ago because mice transplanted with mixtures of allogeneic BM and T cells developed severe skin, gut, and lung lesions that were associated with high levels of TNF-α messenger RNA (mRNA) in these tissues. Target organ damage could be inhibited by infusion of anti–TNF-α mAbs, and mortality could be reduced from 100% to 50% by the administration of the soluble form of the TNF-α receptor (sTNFR), an antagonist of TNF-α. Accumulating experimental data further suggest that TNF-α is involved in a multistep process of GVHD pathophysiology. TNF-α can (1) cause cachexia, a characteristic feature of GVHD; (2) induce maturation of DCs, thus enhancing alloantigen presentation; (3) recruit effector T cells, neutrophils, and monocytes into target organs through the induction of inflammatory chemokines; and (4) cause direct tissue damage by inducing apoptosis and necrosis. TNF-α also involves in donor T-cell activation directly through its signaling via TNFR1 and TNFR2 on T cells. TNF-TNF1 interactions on donor T cells promote alloreactive T-cell responses and TNF-TNFR2 interactions are critical for intestinal GVHD. TNF-α also seems to be an important effector molecule in GVHD in skin and lymphoid tissue. In addition, TNF-α might also be involved in hepatic GVHD, probably by enhancing effector cell migration to the liver via the induction of inflammatory chemokines. An important role for TNF-α in clinical acute GVHD has been suggested by studies demonstrating elevated serum levels or TNF-α or elevated TNF-α mRNA expression in peripheral blood mononuclear cells in patients with acute GVHD and other endothelial complications, such as hepatic VOD.

The second major proinflammatory cytokine that appears to play an important role in the effector phase of acute GVHD is IL-1. Secretion of IL-1 appears to occur predominantly during the effector phase of GVHD of the spleen and skin, two major GVHD target organs. A similar increase in mononuclear cell IL-1 mRNA has been shown during clinical acute GVHD. Indirect evidence of a role for IL-1 in GVHD was obtained with administration of this cytokine to recipients in an allogeneic murine BMT model. Mice receiving IL-1 displayed a wasting syndrome and increased mortality that appeared to be an accelerated form of disease. By contrast, intraperitoneal administration of IL-1 receptor antagonist (IL-1RA) starting on day 10 posttransplant was able to reverse the development of GVHD in the majority of animals, providing a significant survival advantage to treated animals. However, the attempt to use IL-1RA to prevent acute GVHD in a randomized trial was not successful.

As a result of activation during GVHD, macrophages also produce NO, which contributes to the deleterious effects on GVHD target tissues, particularly immunosuppression. NO also inhibits the repair mechanisms of target tissue destruction by inhibiting proliferation of epithelial stem cells in the gut and skin. In humans and rats, the development of GVHD is preceded by an increase in serum levels of NO oxidation products.

IL-6 has also been identified as a critical cytokine that promotes a proinflammatory response during GVHD and inhibits the reconstitution of Tregs. Although Tawara and colleagues confirmed an important role for IL-6 in GVHD, their findings were independent of T effector cell expansion or donor Treg responses. It is possible that reduction in GVHD is a consequence of direct reduction in IL-6–induced inflammation and cytopathic damage of the target tissues. Existing data demonstrate important roles for various inflammatory effectors in GVHD. However, the relevance of currently studied or as yet unknown specific effectors might be determined by other factors, including the intensity of preparatory regimens, the type of allograft, the T-cell subsets and the duration of BMT. In any event, both experimental and clinical data suggest an important role for both the cellular and inflammatory mediators in GVHD-induced target organ damage.

BIOMARKERS OF GRAFT-VERSUS-HOST DISEASE

Large datasets have identified and validated plasma biomarkers with important prognostic value at the onset of symptoms and treatment of acute GVHD. Several initial reports based on proteomic discovery of plasma samples taken from patients with systemic GVHD initially described markers including IL-2Rα, TNFR1, IL-8, and hepatocyte growth factor (HGF). Elafin has been identified as a biomarker specific for skin GVHD, and regenerating islet-derived 3α (REG3α) as a biomarker of GI GVHD, and ST2 or the soluble IL-33 receptor as a maker of resistance to therapy. Subsequently, in an effort to improve diagnostic precision panels that combine three plasma biomarkers (TNFR1, ST2, and Reg3α) were used in the creation of an algorithm that computed the probability of nonrelapse mortality for individual patients.[17] The algorithm was developed in a multicenter training set and two separate multicenter validation sets, respectively. The investigators identified thresholds that created three distinct Ann Arbor GVHD scores. In all three datasets (training, test, and validation), the cumulative incidence of 6-month nonrelapse mortality significantly increased as the Ann Arbor GVHD score increased: 8% for score 1, 27% for score 2, and 46% for score 3 ($P < .0001$). Conversely, the response to primary GVHD treatment decreased as the GVHD score increased: 86% for score 1, 67% for score 2, and 46% for score 3 ($P < .0001$). Two-biomarker algorithms involving only ST2 and REG3α have demonstrated similar value to the aforementioned three marker panels and were predictive of corticosteroid resistance associated with elevated TRM.[18]

These biomarkers may also provide new insights into the biology of GVHD. For example, the IL-22–Reg3 axis protects the epithelial barrier function of the intestinal mucosa. ISCs are principal cellular targets of GVHD in the GI tract, whereas discussed previously certain strains of intestinal flora are critical for amplification of GVHD damage. ISCs are protected by antibacterial proteins such as REG3 α secreted by neighboring Paneth cells. Mucosal barrier disruption caused by stem cell dropout and subsequent lack of mucosal regeneration may preferentially allow Paneth cell proteins, including REG3 α, to traverse into the bloodstream. Other groups have extended biologic links between intestinal immunologic injury and biomarkers. For instance, the number of Paneth cells themselves in duodenal biopsies for GVHD, which can be eliminated during intestinal crypt damage during GVHD, has been shown to correlate with response to treatment and survival.[9] Similarly, high plasma levels of amphiregulin, a plasma EGFR ligand involved in GI mucosal repair, has been shown to be elevated at GVHD onset in patients with poor subsequent outcomes.[19] Finally, as a consequence of early mucosal barrier permeability the concentration of certain stool analytes such as α_1-antitrypsin and calprotectin are elevated in the setting of intestinal injur,[20] although to date the diagnostic utility of these markers is less developed in clinical settings.

These findings suggest that biomarker-based scores might one day be used to guide risk-adapted therapy strategies, together with clinical staging, when acquired at the onset of acute GVHD. For example, high-risk patients are candidates for intensive primary therapy, whereas low-risk patients are candidates for rapid tapers of systemic steroid therapy. Whether any such markers can be successfully integrated into prospective trials in real time and the degree to which modulating the intensity of frontline therapy can successfully ameliorate the natural history of high risk GVHD remain to be determined.

Determining patients at risk of significant morbidity and mortality in chronic GVHD remains a significant unmet need. However, at this time no biomarkers of chronic GVHD have been reliably validated in clinical studies. This likely reflects the relative complexity of accurately characterizing the various subforms of chronic GVHD in addition to the understanding of underlying chronic GVHD biology. Nonetheless, some promising candidates are beginning to emerge. CXCL9 has been identified and validated in several hundred patients from at least two HCT centers. Other biomarkers with potential utility include soluble B-cell activation factor (sBAFF), anti-double strand DNA antibody, soluble IL-2 receptor-α (sIL-2Rα), and soluble CD13 (sCD13); sBAFF and anti-dsDNA also may be elevated in patients with late-onset chronic GVHD, but these biomarkers need to be validated in much larger cohorts before definitive conclusions can be drawn.

Prevention of Acute Graft-Versus-Host Disease

Elimination of T cells with mAbs, immunotoxins, lectins, CD34 columns, or physical techniques are effective at reducing GVHD. A typical unmanipulated marrow transplant entails the infusion of approximately 10^7 T cells per kg of recipient weight. A T-cell dose 10^5 or less per kg has been associated with complete control of GVHD. More recently, the combination of very high stem cell numbers and less than 3×10^4 CD3 cells/kg allowed haploidentical transplantation without GVHD. Presumably, host immune cells that survive the initial conditioning are responsible for graft rejection. When the stem cell source contains a large numbers of T cells, the GVH reaction further reduces the residual population capable of host versus graft alloreactivity, thus decreasing graft rejection. To some degree, the higher graft failure rates may be controlled by increasing the intensity of the immunosuppression of the conditioning regimen or by adding back T cells. Overall there has been no improvement in survival that can be definitively attributed to T-cell depletion.

Evolution of Modern Clinical Graft-Versus-Host Disease Prevention Strategies

Treatment of established GVHD with specific T-cell antibodies has produced mixed results. Although antithymocyte globulin has definite activity in established GVHD and prevention of GVHD, the nonspecific clearance of T cells may result in increased opportunistic infections and no improvement in survival. More specific therapies targeting single cytokines or immune cell subsets with humanized anti–IL-2 receptor antibody daclizumab or the humanized anti-CD3 antibody visilizumab were initially promising because they offer the potential of selectively removing the activated T cells. However, an increased risk for infection or relapse may still be observed; thus improvement in overall survival has been less clear.

The first generally prescribed GVHD preventive regimen was the administration of intermittent low-dose methotrexate as developed in a dog model by Thomas and Storb. The principle of this approach was to administer low dosages a cell cycle–specific chemotherapeutic agent immediately after the transplant, when the T cells have started to divide after exposure to allogeneic antigens. Subsequently, the addition of antithymocyte globulin, prednisone, or both resulted in incremental improvement in the GVHD rate but no improvement in survival. Ultimately, the course of methotrexate was abbreviated and combined with a T-cell activation inhibitor, such as CSP or tacrolimus. The introduction of CSP in the late 1970s was a significant advance in GVHD prevention. A similar agent, tacrolimus, has been shown to provide similar control of GVHD. As a single agent, CSP was about as effective as methotrexate. However, in combination with methotrexate, there was a significant reduction in the incidence of GVHD and an improvement in survival. Subsequent trials of tacrolimus and methotrexate compared with CSP and methotrexate showed no clear advantage for either combination. The addition of prednisone to the conventional two-drug regimen resulted in similar rates of GVHD and no improvement in survival.

Sirolimus (rapamycin) is a macrocyclic lactone immunosuppressant that is similar in structure to tacrolimus and CSP. All three drugs bind to immunophilins; however, sirolimus complexed with FKBP12 inhibits T-cell proliferation by interfering with signal transduction and cell cycle progression and can prevent GVHD. Because sirolimus acts through a separate mechanism from the tacrolimus-FKBP complex (and CSP -cyclophilin complex), it is synergistic with both tacrolimus and CSP. In addition, mycophenolate mofetil (MMF) has been studied as a substitute for methotrexate particularly as a component of reduced intensity regimens based on the premise that this may limit cytotoxic effects on mucosal tissues thereby limiting early mucositis. MMF is the prodrug of mycophenolic acid (MPA), a selective inhibitor of inosine monophosphate dehydrogenase, an enzyme critical to the de novo synthesis of guanosine nucleotide. Because T lymphocytes are more dependent on such synthesis than myeloid or mucosal cells, MPA preferentially inhibits proliferative responses of T cells. To date, prospective comparisons between either MMF and MTX combined with calcineurin inhibitors are lacking, but meta-analysis have not clearly suggested superiority of either approach. HLA barriers have historically restricted transplantation of haploidentical donors using conventional calcineurin inhibitor–based GVHD prophylaxis due to high rates of graft failure and grade III to IV GVHD. However, the addition of posttransplant cyclophosphamide (PtCy) has recently emerged as a standard component of acute GVHD prophylaxis regimens in haploidentical HCT, likely due to deletion of alloreactive T cells without eliminating $CD34^+$ stem cells that are thought to be protected by expressing high levels of aldehyde dyhyrogenase.[21] In these HLA-mismatched situations, PtCy together with tacrolimus and MMF results in stable engraftment and low rates of grade III to IV acute GVHD and chronic GVHD. Current prospective studies are now comparing PtCy to standard tacrolimus/MTX-based prevention regimens in HLA-matched HCT.[22] A major consequence of this advance is the improved availability of donor options in critically underrepresented ethnic groups.

Therapy for Acute Graft-Versus-Host Disease

Glucocorticoid steroids are the initial therapy for acute GVHD. The mechanisms by which steroids work are multifactorial; they act as lympholytic agents and inhibit the release of inflammatory cytokines such as IL-1, IL-2, IL-6, IFN-γ, and TNF-α. Because of its intravenous (IV) availability, methylprednisolone is the steroid most commonly given for acute GVHD. Various dosing regimens have been used, none of which is clearly superior. High-bolus doses (10 to 20 mg/kg or 500 mg/m^2) may have higher initial response rates, but flares on tapering and opportunistic infections are common. Both the Seattle and Minnesota transplant groups have found that treatment with steroids was as effective as, or more effective than, other therapies or combination of therapies, with 20% to 40% of patients having durable long-term responses. Long-term salvage rates for patients who did not respond to steroids were 20% or less; most patients eventually died from infection, acute GVHD, and/or chronic GVHD. Clinically, two types of failure of corticosteroid treatment of acute GVHD can be distinguished: true steroid resistance (i.e., progression of GVHD symptoms and manifestations while patients are receiving full-dose corticosteroid treatment) and steroid dependence (i.e., reoccurrence [or flare] of GVHD during or after tapering of steroid treatment). In general, the prognosis with true steroid-resistant GVHD is worse than the prognosis of steroid-dependent patients. A comparison of trials dealing with steroid-resistant GVHD is hampered by variable inclusion of both patient groups in many of these trials. A number of agents have been tested, including chemical immunosuppressants such as MMF, antithymocyte globulin (ATG), anti-CD3 anti–T-cell antibodies, and more specific agents directed against activation or adhesion molecules anti-CD25, anti-CD147, or cytokines or extracorporeal photopheresis. Similarly, a recent head-to-head prospective phase III trial assessing the IL-2 receptor antibody inolimumab, when compared with ATG, did not show superiority for either agent with respect to survival.[23] A number of other promising phase II trials have also suggested a role for more selective approaches such as TNF inhibition when added to steroids in treating GVHD; however, a randomized trail failed to demonstrate any difference when compared with the addition of pentostatin or anti–IL-2 to steroids and was inferior to the addition of MMF. It should be noted that a follow-up trial for frontline therapy comparing MMF with corticosteroids versus corticosteroids alone was ended prematurely due to lack of efficacy with combination therapy. More recently, based on preliminary studies in the setting of steroid-refractory acute GVHD, IL-6 antagonism has been adopted at some centers as a treatment for steroid-refractory acute GVHD but controlled studies for this agent are presently lacking.[24]

Considering the overlapping roles that individual cytokines play in the complex immune biology, such approaches may be limited in their capacity to treat aggressive forms of GVHD. These trials also underscore the challenges in improving outcomes in treatment of established GVHD whereby potentially irreversible underlying damage to tissues that can complicate a full recovery.

A recent advance in GVHD treatment has been licensing of the JAK1/2 inhibitor ruxolitinib as the first US Food and Drug Administration (FDA)-approved therapy for SR-GVHD. This agent targets multiple pathways distal to cytokine-regulated signaling via small molecule tyrosine kinase inhibition of JAKs and STATs that has demonstrated some success in treating SR-GVHD. After high response rates were observed in a retrospective survey, a prospective, open label, multicenter trial of the JAK1/2 inhibitor ruxolitinib reported more than half of SR-GVHD patients met the primary end point of day 28 overall response, including a median duration of response of approximately 1 year.[25] As alluded to previously, given the lack of randomized data, this approach will require careful monitoring, especially considering blood cytopenias and infections can frequently complicate this treatment in severe GVHD.

CHRONIC GRAFT-VERSUS-HOST DISEASE

Chronic GVHD was initially defined as a GVHD syndrome presenting more than 100 days after transplant; its onset occurred either as an extension of acute GVHD (overlap), after a disease-free interval (quiescent), or with no precedent (de novo). Chronic GVHD may be limited or extensive (see Table 109.3). Any grade of acute GVHD increases the probability of chronic GVHD, although no singular pathologic feature of the former predicts the development of the latter. Its incidence ranges from 30% to 60% after transplantation with the bone marrow, and with increased prevalence after peripheral blood progenitor transplants.

As with acute GVHD, the immune system appears to be affected in all patients, who are highly susceptible to bacterial, viral, fungal, and opportunistic infections. Specific abnormalities of cellular immunity include decreases in the production of antibodies against specific antigens, defects in the number and function of CD4$^+$ T cells, and increases in the number of nonspecific suppressor cells, which further diminish lymphocyte responses. Skin changes resembling widespread lichen planus with papulosquamous dermatitis, plaques, desquamation, dyspigmentation, and vitiligo occur in 80% of patients. Destruction of dermal appendages leads to alopecia and onychodysplasia. Severe chronic GVHD of the skin can resemble scleroderma, with induration, joint contractures, atrophy, and chronic skin ulcers. Chronic cholestatic liver disease occurs in 80% of patients and often resembles acute GVHD; it rarely progresses to cirrhosis. Severe mucositis of the mouth and esophagus can result in weight loss and malnutrition. However, intestinal involvement is infrequent and, when involved, typically affects the upper GI tract with stricturing. Chronic GVHD also produces a sicca syndrome, with atrophy and dryness of mucosal surfaces caused by lymphocytic destruction of exocrine glands, usually affecting the eyes, mouth, airways, skin, and esophagus. The hematopoietic system may also be affected, and thrombocytopenia is an unfavorable prognostic factor in patients with chronic GVHD. Important predictors of unfavorable outcome are progressive onset, lichenoid skin changes, elevated serum bilirubin level, continued thrombocytopenia, and failure to respond to 9 months of therapy. Among patients with none of these risk factors, 70% are expected to survive, compared with less than 20% with two or more of these risk factors.

Histologic examination of the immune system reveals involution of thymic epithelium, disappearance of Hassall corpuscles, depletion of lymphocytes, and absence of secondary germinal centers in lymph nodes. Pathologic skin findings include epidermal atrophy with changes characteristic of lichen planus and striking inflammation around eccrine units. Sclerosis of the dermis and fibrosis of the hypodermis subsequently develop. GI lesions include localized inflammation of the mucosa and stricture formation in the esophagus and small intestine. Histologic findings in the liver are often similar to those that occur in acute GVHD but are more intense, with chronic changes such as fibrosis and hyalinization of portal triads, obliteration of bile ducts, and hepatocellular cholestasis. The endocrine glands of the eyes, mouth, esophagus, and bronchi show destruction focused on centrally draining ducts, with secondary involvement of alveolar components. Findings of bronchiolitis obliterans, similar to those that occur in rejection of lung transplants, are now generally considered a pulmonary manifestation of chronic GVHD, although the pathogenesis of this process remains unclear.

Clinical Manifestations of Chronic Graft-Versus-Host Disease

Chronic GVHD can present with a plethora of clinical manifestations. Because of its unpredictable pattern and the late onset, when patients are no longer receiving care at their transplant center, the diagnosis is often delayed or not recognized. However, multiorgan diagnostic criteria developed by the National Institutes of Health (NIH) is now the accepted as the standard for diagnosing and evaluating responses in most clinical trials and research settings for chronic GVHD.

Dermatologic

Skin involvement in chronic GVHD presents with varied features. Lichenoid chronic GVHD presents as an erythematous, papular rash that resembles lichen planus with no typical distribution pattern. Sclerodermatous GVHD may involve the dermis and/or the muscular fascia and clinically resembles systemic sclerosis. The skin is thickened, tight, and fragile, with very poor wound healing. Either hypopigmentation or hyperpigmentation may occur. In severe cases the skin may become blistered and ulcerate. Hair changes can include increased brittleness, premature graying, and alopecia. Fingernails and toenails may also be affected by chronic GVHD. Destruction of sweat glands can cause hyperthermia.

Ocular

Ocular GVHD usually presents with xerophthalmia or dry eyes. Irreversible destruction of the lacrimal glands results in dryness, photophobia, and burning. Local therapy with preservative-free tears and ointment or the placement of punctal plugs by an ophthalmologist might be required. Conjunctival GVHD, a rare manifestation of severe chronic GVHD, has a poor prognosis.

Oral

Oral GVHD causes xerostomia and/or food sensitivity. More advanced disease may cause odynophagia due to esophageal damage and strictures, although esophageal involvement occurs rarely without oral disease. Physical examination may reveal only erythema with a few white plaques, prompting a misdiagnosis of thrush or herpetic infections. Lichenoid changes in advanced disease can cause extensive plaque formation.

Gastrointestinal

Patients with chronic GVHD have GI complaints that mimic other disease states, including acute GVHD, infection, dysmotility, lactose intolerance, pancreatic insufficiency, and drug-related side effects. In one retrospective review of the intestinal biopsies of patients with chronic GVHD and persistent GI symptoms, a majority of patients had evidence of both acute and chronic GVHD, and only 7% of the patients had isolated chronic GVHD. Thus, although chronic GVHD may involve the GI tract alone, it may be difficult to diagnose in those circumstances without concurrent acute GVHD.

Hepatic

Hepatic disease typically presents as cholestasis with elevated serum levels of alkaline phosphatase and bilirubin. Isolated hepatic chronic GVHD has become more common with the increasing use of donor lymphocyte infusions. Liver biopsy is required to confirm the diagnosis of chronic hepatic GVHD in patients with no other target organ involvement.

Pulmonary

Bronchiolitis obliterans is a late and serious manifestation of chronic GVHD. Patients typically present with a cough or dyspnea. Severe sclerotic disease of the chest wall may also give rise to similar symptoms with no intrinsic pulmonary disease. Pulmonary function tests demonstrate obstructive physiology and a reduction in diffusion capacity (DLCO). Chest computed tomography results may be normal or may show hyperinflation with a ground-glass appearance. Overall, patients with bronchiolitis obliterans have minimal response to therapy and a very poor prognosis. Patients with chronic GVHD are also at risk for chronic sinopulmonary infections, but symptoms may be minimal.

Hematopoietic

Cytopenias in chronic GVHD are common. This may be a result of stromal damage, but autoimmune neutropenia, anemia, and/or thrombocytopenia are also seen. Thrombocytopenia at the time of chronic GVHD diagnosis is associated with poor prognosis. However, thrombocytopenia post transplant is a poor prognostic factor regardless of GVHD, and eosinophilia is occasionally seen with chronic GVHD.

Immunologic

Chronic GVHD is inherently immunosuppressive. Functional asplenia with an increased susceptibility to encapsulated bacteria is common and circulating Howell-Jolly bodies can be seen on peripheral blood smear. Patients are also at risk for invasive fungal infections and *Pneumocystis carinii* pneumonia (PCP). Hypoglobulinemia is common, and patients with levels less than 500 mg/dL should be supplemented with IV Ig.

Musculoskeletal

Fascial involvement in sclerodermatous GVHD is usually associated with skin changes. Fasciitis in joint areas can cause severe restriction of range of motion. Muscle cramps are a common complaint in patients with chronic GVHD, but myositis with elevated muscle enzymes is rare. Many patients with chronic GVHD are on steroid therapy and have low levels of sex hormone posttransplant. Thus avascular necrosis, osteopenia, and osteoporosis are frequent complications.

Although several cases have been described, it is yet to be determined in large studies whether kidney involvement and associated nephrotic syndrome, which are primary targets in some animal models of chronic GVHD, are also involved. Among the myriad clinical features of chronic GVHD, three definitive signs appear to be risk factors for increased mortality: (1) extensive skin GVHD involving greater than 50% of the body surface area, (2) platelet count of less than 100,000/μL, and (3) progressive onset and acute GVHD that continues uninterrupted beyond day 100. However, chronic GVHD remains, except in cases with obvious features, a difficult diagnosis; response to therapy is even more difficult to assess. Recent criteria established by an NIH consensus conference might prove to be beneficial in establishing uniform guidelines for diagnosis, treatment, and response.

Differential Diagnosis

The distinction between chronic and acute GVHD has been traditionally based on the time of onset. However, with the advent of low-intensity HCT, that distinction has become less relevant. The NIH Working Group has, in addition to the two main categories of GVHD, added two subcategories. The broad category of acute GVHD includes (1) classic acute GVHD (maculopapular rash, nausea, vomiting, anorexia, profuse diarrhea, ileus, or cholestatic hepatitis), occurring within 100 days after transplantation or DLI (without diagnostic or distinctive signs of chronic GVHD), and (2) persistent, recurrent, or late acute GVHD: features of classic acute GVHD without diagnostic or distinctive manifestations of chronic GVHD occurring beyond 100 days of transplantation or DLI (often seen after withdrawal of immune suppression). The broad category of chronic GVHD includes (1) classic chronic GVHD without features characteristic of acute GVHD and (2) an overlap syndrome in which features of chronic and acute GVHD appear together. In the absence of histologic or clinical signs or symptoms of chronic GVHD, the persistence, recurrence, or new onset of characteristic skin, GI tract, or liver abnormalities should be classified as acute GVHD regardless of the time after transplantation. With appropriate stratification, patients with persistent, recurrent, or late acute GVHD or overlap syndrome can be included in clinical trials with patients who have chronic GVHD.

CHRONIC GRAFT-VERSUS-HOST DISEASE: PATHOPHYSIOLOGY

The pathophysiology of chronic GVHD is generally much less well understood than that of acute GVHD and has undergone less intensive experimental modeling. It is important to recognize that chronic GVHD was originally defined as a temporal rather than a clinical or pathophysiologic entity. The initial clinical reports of chronic GVHD described abnormalities that occurred at least 150 days after stem cell infusion. By convention, day 100 after stem cell infusion is used as an arbitrary divider between acute and chronic GVHD. However, some manifestations of acute GVHD occur after day 100, and some manifestations of chronic GVHD may occur before day 100. Thus it is preferable to consider the clinical symptoms and signs per se rather than their timing of onset.

Relatively little is known about the pathophysiology of chronic GVHD. This is due in part to the absence of appropriate animal models that can capture the kinetics and the protean manifestation of chronic GVHD. Based on certain clinical features, chronic GVHD has been considered to be an autoimmune disease, with some experimental data suggesting that chronic GVHD results from defective central negative selection, which leads to the generation of autoreactive clones that escape tolerogenic mechanisms operating in the periphery.

This would indicate that the nonpolymorphic antigens expressed in both the donor and recipient rather than MiHA antigens are the likely targets. In contrast to T cells from animals with acute GVHD that are specific for host alloantigens, T cells from animals with chronic GVHD are specific for a public (common) determinant of MHC class II molecules. These T cells are considered autoreactive because they recognize public MHC class II determinants that are common to both donor and recipient rather than polymorphic histocompatibility antigens that are specific for the host. The autoreactive cells of chronic GVHD are associated with a damaged thymus, which can be injured by several mechanisms, including acute GVHD, the conditioning regimen, or age-related involution and atrophy. In chronic GVHD the ability of the thymus to delete autoreactive T cells (negative selection) and to induce tolerance is impaired. However, no clear data exist on the isolation of “autoreactive” donor-derived T-cell clones that equally recognize nonpolymorphic antigens from the donor and recipient cells. However, this does not directly preclude the existence of a causative role for autoreactive T cells. Chronic GVHD could also be a product of T cells that have undergone relatively chronic antigen stimulation as a result of the presence of inexhaustible and ubiquitous MiHA antigens. Allo-T cells under circumstances of chronic MiHA antigen stimulation can induce syndromes resembling those induced by the chronic antigen stimulation in autoimmune diseases. This concept is also consistent with the proposal of acute GVHD as a risk factor for chronic GVHD. The antigens targeted in chronic GVHD could be the same dominant ones targeted in acute GVHD, but the reactive T cells could be different; for example, they may secrete TGF-β. However, antigens other than those that were initially immunodominant (even those not initially targeted but introduced through epitope spread of either the nonpolymorphic “autoantigens” or the now-distinct MiHAs) could be important. It is also conceivable that regulatory mechanisms could frequently fail in allo-HCT, resulting in activation and expansion of T cells that recognize both nonpolymorphic and MiHA epitopes. One recent murine study suggested that development of chronic GVHD-like syndrome is target antigen-dependent. Furthermore, chronic GVHD pathogenesis could, in part, be a consequence of T cell priming by donor-derived APCs. In some patient subsets, responses to rituximab, presence of MiHA-specific antibodies, and the presence of chronic GVHD after T cell–depleted (TCD) allo-BMT would indicate that, in addition to donor T cells, donor B cells might be a direct effector or might have a role in priming T cells as APCs. Given the myriad clinical presentations of chronic GVHD that tend to occur at variable times after HCT, it is possible that separate pathogenic mechanisms are involved in causing distinct manifestations and that no single putative mechanism is sufficient to cause chronic GVHD. Nonetheless, a murine model demonstrated a pathogenic role for donor B cells and alloantibody production in causing experimental chronic GVHD.

THERAPY FOR CHRONIC GRAFT-VERSUS-HOST DISEASE

Chronic GVHD has a major impact on both quality of life and survival, frequently involves multiple organs, and necessitates prolonged immunosuppressive therapy. One report noted that 15% of cancer-free patients were still receiving immunosuppressive therapy after 7 years. The more severe forms of chronic GVHD are clearly associated with a lower disease-free survival. Thus the potential benefit of a GVL effect is shadowed by significant treatment-related mortality.

Current therapies for chronic GVHD have historically been of limited efficacy, particularly for patients who do not respond to frontline steroid-based therapy. A recent development was the FDA approval of the BTK inhibitor ibrutinib for the treatment of chronic GVHD following failure of one or more prior lines of therapy. This was based on an open label prospective design that reported an overall best response rate of 67% by NIH criteria, whereby a majority of responders experienced disease remission for greater than 5 months and cumulative reductions in their dosage of corticosteroids.[26] Another frequently used approach in some centers is ECP, which is thought to modulate alloreactivity of circulating T cells and DCs. Based on systemic review of prospective trials, extracorporeal photopheresis (ECP) demonstrated the greatest clinical effects in patients with cutaneous and GI tract involvement, as well as promoting steroid-sparing effects.[27] Nonetheless, the overall lack of standardized response criteria to measure therapeutic efficacy and the protean nature of this disease pose major obstacles to pursuing therapeutic trials in chronic GVHD. The NIH-sponsored consensus project has provided, for the first time, a set of standardized measures and definitions to use as response criteria in chronic GVHD. The NIH consensus conference has defined response measures classified in two main groups: clinician assessed and patient reported (Table 109.4).

The prevention of acute GVHD has not consistently resulted in a lower incidence of chronic GVHD. A clear example is the use of reduced-intensity transplants, consistently associated with a lower incidence of acute GVHD but with no major impact on chronic GVHD. The extended use of GVHD prophylaxis with CSP, or variations in the CSP dosage used, showed no beneficial effects on the incidence of chronic GVHD. The addition of thalidomide to CSP and methotrexate prophylaxis, the administration of IV Ig, and early treatment based on biopsy findings of subclinical GVHD in an attempt to preemptively treat chronic GVHD were unsuccessful. Currently, only the most-established practices for limiting chronic GVHD have involved use of bone marrow grafts and various methods that significantly deplete T cells in the graft inoculum (ATG, PtCy, CD34$^+$ selection), although as alluded to previously, none of these approaches have clearly established a survival advantage after HCT. The most commonly used therapy to treat chronic GVHD is prednisone. Sullivan and colleagues reported that prednisone alone is superior to prednisone plus azathioprine for primary treatment of patients with chronic GVHD. However, in patients classified as high risk on the basis of platelet counts less than 100,000/μL, treatment with prednisone alone resulted in only 26% 5-year survival. When a similar group of patients was treated with alternating-day CSA and prednisone, 5-year survival exceeded 50%. A recent randomized study of 287 patients with extensive GVHD found no statistically significant difference in nonrelapse death at 5 years or in cumulative incidence of secondary therapy at 5 years when prednisone alone was compared with prednisone plus CSA. For chronic GVHD that recurs or fails to respond to initial therapy, there is no standard treatment. Experimental therapies currently under evaluation include psoralen plus ultraviolet light A, MMF, thalidomide, total lymphoid

TABLE 109.4 National Institutes of Health Chronic GVHD Measures

Measure	Clinician-Assessed	Patient-Reported
Chronic GVHD-Specific Core Measures		
Signs	Organ-specific measures	Not applicable
Symptoms	Clinician-assessed symptoms	Patient-reported symptoms
Global rating	Mild, moderate, or severe	Mild, moderate, or severe
	0–10 severity scale	0–10 severity scale
	7-point change scale	7-point change scale
Chronic GVHD Nonspecific Ancillary Measures		
Function	Grip strength 2-min walk time	Patient-reported function

GVHD, Graft-versus-host disease.

irradiation, extracorporeal photopheresis, pentostatin, and acitretin. (Table 109.5 lists the commonly used GVHD drugs and their side effects.)

SYNGENEIC GRAFT-VERSUS-HOST DISEASE

A GVHD-like syndrome that is usually self-limited and predominantly affects the skin can occur in recipients of syngeneic or autologous transplants. It is also possible that some of the reported cases of syngeneic GVHD have reflected a mistaken assumption that the donor was syngeneic without extensive molecular confirmation. The condition manifests primarily as a rash that usually responds promptly to corticosteroid therapy. Although the level of severity may be grade II or III, the disease generally resolves promptly with the administration of glucocorticoids and is not life-threatening. Virtually all patients in whom a GVHD-like syndrome develops after syngeneic transplantation have been prepared with intensive conditioning regimens, usually involving irradiation. Experimental studies suggest that such conditioning is essential for the induction of thymic dysfunction, which is necessary for the development of the disease. Generation of autoreactive cells (a defect in thymic negative selection) and elimination of regulatory cells appear to be the requirements for the development of this disease. An additional hypothesis is that in some individuals maternal cells transmitted to them during their fetal development remain present throughout adult life. These observations suggest the possibility that, in some instances, small numbers of HLA-incompatible cells (derived from the donor's mother) may be transmitted with HLA-identical transplants. Transplacentally transferred maternal cells may also play a role in the development of neonatal GVHD.

TABLE 109.5 Commonly Administered Drugs for Graft-Versus-Host Disease Prophylaxis and Treatment

Drug	Mechanism	Adverse Effects
Corticosteroids	Direct lymphocyte toxicity; suppress proinflammatory cytokines such as tumor necrosis factor (TNF)-α	Hyperglycemia; acute psychosis; severe myopathy; neuropathy; osteoporosis; cataract development
Methotrexate (MTX)	Antimetabolite: inhibit T-cell proliferation	Significant renal, hepatic, and gastrointestinal toxicities
Cyclosporine A (CSA)	Interleukin (IL)-2 suppressor; blocks Ca^{2+}-dependent signal transduction distal to T-cell receptor (TCR) engagement	Renal and hepatic insufficiency; hypertension; hyperglycemia; headache; nausea and vomiting; hirsutism; gum hypertrophy; seizure with severe toxicity
Tacrolimus (FK506)	IL-2 receptor; blocks Ca^{2+}-dependent signal transduction distal to TCR engagement	Similar to CSA
Mycophenolate mofetil (MMF)	Inhibits de novo purine synthesis	Body aches; abdominal pain; nausea and vomiting; diarrhea; neutropenia
Sirolimus	Mammalian target of rapamycin (mTOR) inhibitor	Thrombocytopenia; hyperlipidemia, TTP
Antithymocyte globulin (ATG)	Polyclonal immunoglobulin	Anaphylaxis; serum sickness
JAK inhibitors	Targets multiple pathways distal to cytokine-regulated signaling via small molecule tyrosine kinase inhibition of JAKs and STATs	Blood cytopenias and infections
BTK inhibitors	Irreversible inhibition of both BTK and IL-2–inducible T-cell kinase (ITK) that impairs B-cell and T-cell function, respectively	Blood cytopenias and infections

Transfusion-Associated Graft-Versus-Host Disease

Most blood products administered to immunocompromised patients are now irradiated or at least leukocyte-depleted to avoid the transfusion of viable alloreactive T cells. With most homologous blood products, the MHC incompatibility between donor and recipient results in rapid clearance of transfused T cells by the recipient's immune system. However, occasionally, transfusions from donors who are homozygous for one of the recipient's MHC haplotypes are not recognized as foreign by the recipient. These cells can survive, "engraft," and mount an immunologic attack against the unshared haplotype in the patient, resulting in transfusion-induced GVHD. Transfusion-associated GVHD differs from GVHD occurring after transplantation in terms of kinetics and manifestations (i.e., with transfusion-associated GVHD, the recipient marrow is a major target). Because the number of stem cells in the offending blood product is inadequate, there is no hemopoietic recovery from donor cells. This syndrome is generally fatal as a result of refractory pancytopenia and/or other organ involvement.

GRAFT-VERSUS-LEUKEMIA RESPONSES

The GVL response after allogeneic HCT results from the immunologic attack of the host tissue and, by extension, the leukemia (i.e., the tumor). This response represents a potent form of immunotherapy that circumvents some of the "immunoediting" mechanisms used by tumor cells to develop in the hosts. The power of the alloimmune response to eliminate malignancy was first reported more than 50 years ago in experimental models by Barnes et al. However, GVL as its own entity and its close association with GVHD were not established until another 15 years later.

Clinical Features

Clinical evidence that the donor graft mediates important antileukemic effect comes from higher relapse rates for recipients of syngeneic stem cells than for recipients of HLA-matched sibling grafts. These findings have also been confirmed in a multicenter analysis of HCT recipients with acute myelogenous leukemia (AML) in first remission and subsequent retrospective analyses by the International Bone Marrow Transplant Registry (IBMTR). The second IBMTR analysis also showed that the magnitude of this GVL effect is greater for patients with chronic myelogenous leukemia (CML) and AML and not statistically significant for patients with acute lymphoblastic leukemia (ALL) in first remission.

Several case reports of patients with relapse of leukemia after allogeneic HCT noted remissions of the malignancy either after abrupt withdrawal of immunosuppression or during a flare of acute GVHD. Patients who develop GVHD after allogeneic HCT experience relapse less frequently than similar patients who do not develop clinical disease. GVHD is protective against relapse both for HCT recipients with advanced leukemia and for patients who receive transplants in earlier stages of malignancy. Additional analyses also suggest that the magnitude of the GVL effect appears to be disease and stage specific. Initial reports suggested that chronic GVHD was most protective against relapse, but other analyses demonstrate that acute GVHD is also protective. Based on these reports, newer trials of immunotherapy are designed to include cessation of immunosuppressive therapy (without taper). Withdrawal of immunosuppression can induce a GVL reaction for patients whose malignancy has relapsed after HCT, although such responses tend to occur in a minority of patients, coincide with GVHD, and may be transient in nature without additional consolidation (second HCT or DLI).

Another line of clinical evidence regarding the GVL effect of allogeneic HCT and its tight linkage to GVHD comes from the studies using T-cell depletion of the donor graft. Donor T cells included in the stem cell graft are critical for acute GVHD, and T-cell depletion by various strategies is one of the most successful means of reducing the incidence and severity of GVHD after allogeneic HCT. Unfortunately, although T-cell depletion results in less treatment-related morbidity and mortality, improved overall survival rates have not been reliably demonstrated. This failure is due in large part to a reciprocal increase in the subsequent relapse rate after T-cell depletion, as well as to graft failure and other complications. T-cell depletion increases relapse rates particularly in CML. This observation provides further strong, albeit indirect, evidence that allogeneic donor T cells are important mediators not only of GVHD but also of the GVL properties of the allogeneic stem cell graft. Finally, the most compelling evidence of donor T cells in mediating GVL comes from the observations made from donor lymphocyte infusions (discussed later). The induction of GVL is a complex process.

Genetic Basis

The immunotherapeutic effect that occurs in allo-BMT setting is primarily mediated by allogeneic donor T or NK cells directed against the alloantigens shared by the recipient tumor and target tissues and/or tumor-specific antigens that have the advantage of not being subjected to tolerance mechanisms by the host tumor. Understanding of the exquisite specificity of T-cell responses led to attempts to identify specific antigens that are responsible for the GVL effect. Much of the focus has been on the identification of (1) certain oncogenic viral proteins (because these are absent in normal cells but expressed by transformed tumor cells [certain Epstein-Barr virus (EBV) peptides such as EBNA-1, LMP-1, LMP, LCL]), (2) antigens that are expressed in a tissue-specific fashion (melanoma-specific proteins), and (3) proteins that are overexpressed in tumors (WT1, proteinase 3, survivin, telomerase reverse transcriptase, CYPB1, and HER2/neu). Although these antigens are specific, most T-cell responses to these antigens are limited because of the poor immunogenicity of these proteins, expression on normal cells, defects in the processing or presentation of tumor antigens, or production of factors that disable T-cell responses. Thus clinical attempts to obtain high specificity of T-cell responses have been offset with difficulties in obtaining enough sensitivity and vice versa. Furthermore, given the current concepts of stem cell origins of leukemia and cancers, identification of the immunogenic proteins that are specifically expressed in the malignant stem cells and harnessing T-cell responses to those antigens will be needed for the optimal GVL effect to cure malignancy.

In contrast to the tumor-specific or tumor-associated antigens discussed earlier, alloantigens are not subjected to tolerance mechanisms. Vaccination strategies with autologous T cells using tumor-associated or tumor-specific antigens have yielded disappointing clinical antitumor responses. By contrast, allogeneic HCT has met with remarkable GVL responses, perhaps owing to recognition of minor alloantigens in addition to the tumor-associated antigens. This concept has been demonstrated by recent murine studies, which showed that alloantigen on the tumor cells is required for GVL responses and that the principal targets of GVL are the immunodominant allogeneic MiHAs rather than the tumor-associated antigens. Thus T cells specific for MiHA antigens could provide for a potent GVL effect. Significant progress has been made in the identification of MiHAs that are specifically expressed in the host hematopoietic tissues and therefore might allow for a GVL response without causing GVHD. Together, these results suggest that, in addition to tumor-specific proteins, expression of alloantigens and cognate interactions between donor T cells and the tumor tissues are required for the effective induction of the majority of GVL responses. However, T cells specific for some MiHAs are also responsible for GVHD, and a means of consistently separating the beneficial GVL effect from GVHD has not yet been clinically achieved.

KIR Polymorphisms

The two competing models described earlier, the "mismatched ligand" and the "missing ligand" models for HLA-KIR allorecognition, have been supported by clinical observations of GVL responses in different patient and transplant populations. The former model has been shown to separate GVL and GVHD responses in the context of TCD haploidentical HCT for AML. Even though this model is supported by elegant laboratory studies, it was found to be invalid for ALL and also for AML after unrelated donor HCT with immunosuppression. Recent retrospective clinical data suggest that GVHD and GVL can be separated by the "missing ligand" model in CML/AML and myelodysplastic syndrome patients after TCD HLA-identical sibling HCT. Further validation of either models by clinical prospective studies and a better understanding of the balance between the inhibitory and activating receptor-ligand interaction of the NK cells are needed to adequately exploit the interface between HLA-KIR genetics to separate GVHD from GVL.

Immunobiology of Graft-Versus-Leukemia Responses

Given the tight association of clinical GVHD and GVL, as well as the common biologic principles governing these responses after allogeneic HCT, it is important to discuss the similarities and distinctions between them in the context of the three cellular phases of GVHD.[28]

Phase 1: Activation of Antigen-Presenting Cells

The concept that tumor eradication after allogeneic HCT might not require toxic chemoradiotherapy and could be achieved primarily by the immunotherapeutic effect from the GVL responses has led to the clinical development of nonmyeloablative HCT for hematologic and nonhematologic malignancies. Phase 1 is characterized by the development of cytokine storm–generated danger signals from the conditioning regimen and the subsequent activation of APCs. Experimental data suggested that the reduction in conditioning would attenuate the cytokine storm, lead to the development of mixed donor-host chimerism, and confine the GVH response primarily to secondary lymphoid organs, thus causing less severe GVHD without impairing GVL responses. However, nonmyeloablative HCT has delayed the kinetics but did not reduce the overall incidence of GVHD, and a significant number of patients either failed to respond or relapsed. Furthermore, recent murine and human studies have suggested that homeostatic expansion of T cells in a lymphopenic environment induced by conditioning (as opposed to mere immunosuppression) improves the antitumor efficacy of adoptively transferred syngeneic or autologous T cells by increasing the availability of space, enhancing the memory responses, and reducing the competition for homeostatic cytokines (e.g., IL-7 and IL-15) for transferred T cells while eliminating Tregs. Thus low-intensity HCT clearly demonstrates the principle of GVL effect, but the roles of cytokine storm and homeostatic expansion of allogeneic T cells in shaping the intensity of GVL responses are not known.

Host and donor APCs are critical for the induction and severity of GVHD.[8] Activation of APCs is the key step in phase 1 of GVHD. Significant progress has been made in understanding the role of APCs in GVL. Recent experimental evidence has demonstrated a crucial role for professional host APCs in the induction of GVL responses mediated by donor T cells, even when the tumor cells showed some features of APCs. Tumors that merely express costimulatory molecules may still be unable to stimulate an effective immune response because of their various "immunoediting" processes that cause ineffective antigen presentation. However, when the tumor cell itself functions as a professional APC, as with CML, it can generate an effective GVL response. By contrast, cancers such as acute leukemias that seldom differentiate into APCs generate poor GVL responses. Data also demonstrated that given sufficient time and a low tumor burden, cross-presentation of tumor-associated antigens and/or alloantigens by professional donor APCs can occur and may promote or sustain GVL responses by maintaining or expanding alloreactive T cells after initial priming on host APCs. This concept is consistent with clinical GVL responses in CML in which the final stage of a GVL response to CML may be the result of donor T cells responding not directly to the small number of CML stem cells or progenitors (which would be undifferentiated and therefore poor APCs) but to tumor antigens cross-presented on professional donor APCs. Emerging data suggest that enhancing such cross-presentation is sufficient to elicit effective GVL responses against acute or advanced leukemia. However, these data suggest that GVL responses generated after low-intensity conditioning may not be as robust as those after full intensity HCT and highlight the need for a clearer understanding of the effects of cytokine storm and lymphopenia generated danger signals on the activation of APCs in mediating GVL.

Phase 2: Donor T Cell Activation

The core of GVL responses, as with GVHD, is also dependent on the activation of appropriate numbers of T cells. The "second" signals from professional APCs (or certain tumor cells that function as effective APCs) are critical for generating an effective GVL response. Several of the costimulatory pathways that modulate GVHD have also been evaluated in mediating GVL responses. Blockade of CD28 costimulation preserved GVL responses but reduced GVHD in murine studies. However, when the tumor cells also expressed B7 molecules, such blockade reduced the GVL responses. Ex vivo blockade of CD40-CD40L interaction has been shown to reduce GVHD by generating Tregs but still preserve GVL. By contrast, blockade of the 4-1BB pathway reduced both GVHD and GVL. The other costimulatory molecules (OX40 and ICOS) and the inhibitory molecules (CTLA-4 and PD-1) also modulate antitumor responses. A better understanding of the context (i.e., low intensity or DLI) and the hierarchy of timing, duration, and extent of costimulatory requirements of donor T-cell subsets might allow for balancing the intensity of GVL and GVHD responses. Clinical and experimental evidence suggests that donor T cell numbers correlate with the severity of GVHD and GVL responses. TCD grafts had reduced GVHD but increased disease relapse, suggesting a role for T-cell numbers in GVL responses as well. Clinical attempts to separate GVHD and GVL by regulating allogeneic T cell dose have met with limited success. For example, administration of 1×10^5 T cells/kg after HLA-matched sibling transplantation did not mediate GVL effects and yet was associated with a measurable incidence of GVHD. Thus infusion of right numbers of donor T cell effectors is crucial for GVL responses. This has been demonstrated by durable responses that are observed in CML and other malignancies after DLI (see later), despite the experimental evidence that host APCs stimulate a stronger GVL response than do donor APCs. This could be because, clinically, DLI is almost always given without immunosuppression to an individual who has not developed GVHD either from the chemical immunosuppression or physical removal of donor T cells from the allograft. This lack of immunosuppression after DLI increases the likelihood of a GVH response, and DLI is almost always associated with clinical GVHD. The delivery of additional allogeneic effector cells in DLI also increases the effector:target ratio compared with the time of initial HCT. The latter is also clinically demonstrated by a more effective GVL response to DLI against minimal residual disease (BCR-ABL positivity by polymerase chain reaction [PCR]) compared with the response against high leukemic burden (e.g., blast crisis) in CML patients. Thus DLI provides the proof in principle for the concepts that sufficient T-cell numbers and appropriate antigen presentation are required for both GVHD and an effective GVL response.

T-Cell Subsets

Most experimental studies have implicated donor $CD8^+$ T cells as the primary mediators of GVL, but there are no clinical data for $CD8^+$-mediated GVL responses in the absence of $CD4^+$ T cells. Moreover, some clinical data suggest a role for greater CD4-mediated GVL responses without an increase in GVHD after allogeneic HCT and DLI, but it is unclear whether $CD4^+$ T cell–initiated GVL responses occur in the absence of generation of MiHA-specific $CD8^+$ T cells. Given the critical requirement of alloantigens for most GVL responses, the specific requirement of CD4 and/or CD8 T cells for GVL and GVHD is likely to be determined by the expression of the relevant immunodominant MiHAs and/or tumor-associated proteins. Therefore it is unlikely that GVHD and GVL responses can be separated under all circumstances merely by depletion of either subset of alloreactive T cells. However, experimental data suggest it might be possible to separate GVHD and GVL when certain donor T-cell subsets are either depleted or infused (DLI) at appropriate interval after transplant. But the optimal time interval, if any, after clinical HCT is yet to be determined.

Because of recent identification and understanding of the role of various T-cell subsets in mediating immune responses, depletion of specific T-cell subsets to separate GVHD and GVL remains an area of active investigation. For example, recent experimental data suggest that CD62L-expressing naïve T cells home to secondary lymph nodes and are critical for initiating GVHD. In contrast, CD62L-negative effector memory T cells with enhanced reactivity to recall antigens mediated GVL responses with minimal GVHD. An important caveat to these data is the fact that the lack of a priori knowledge of the repertoire of human memory T cells would make it difficult to predict whether these cells might cross-react only with tumor-associated antigens or with the recipient's alloantigens. Using CD62L status alone as determinant of GVHD potential can also have other unintended consequences; recent studies have demonstrated that its expression is critical for the regulation of GVHD by Tregs (see later). Moreover, it is not known whether the behavior of human memory T cells parallels that of murine memory T cells in their migratory, functional, and cytolytic capabilities. Although Tregs reduce antitumor immunity in murine models and in human subjects, experimental data suggest that administration of donor-type Tregs either at the time of HCT or when delayed reduced GVHD but preserved $CD8^+$-mediated perforin-dependent GVL responses. Similar preservation of experimental GVL was also observed by harnessing donor NKT function with G-CSF analogs. However, it remains unclear whether these observations are valid after clinical HCT when the GVL responses might not be entirely dependent on $CD8^+$ T cells.

T-Cell Migration

It is conceivable that manipulation of these interactions to focus the alloimmune response to lymphohematopoietic tissues would enhance GVL responses but not GVHD. For example, blockade of CCR9 ligand TECK or CCR5 and CCL17 may prevent the migration of donor T cells to GI tract and skin, respectively, but preserve GVL. Pharmacologic manipulation with the immunosuppressive agent FTY720 has recently provided the proof in principle for this approach. Given the redundancy, strategies to modulate the chemokine biology for separation of GVHD and GVL will require greater understanding of these networks in modulating the migration not only of specific T-cell subsets but also of the other immune cells in the context of different conditioning regimens.

Phase 3: Effector Phase of Graft-Versus-Leukemia

The effector arm of GVL is also characterized primarily by the antigen-specific cellular components and less by the inflammatory components of alloresponse. Experimental data demonstrate that neutralization of IL-1α reduced GVHD but preserved GVL. By contrast, donor TNF-α secretion contributes to both GVHD and GVL effects, and in some cases, antagonism of TNF-α reduced GVHD and GVL responses. Nonetheless, antagonism of nonspecific inflammatory effectors (e.g., either IL-1 or TNF-α) appears to regulate GVHD to a greater extent than GVL responses after experimental allogeneic HCT.

Several lines of experimental and clinical data demonstrate that antigen-specific donor T-cell subsets and NK cells are the key effectors of GVL. The cytotoxic pathways that are operative in the NK and T cell–mediated antitumor responses have been well characterized. Fas-mediated CTL of tumor targets is used by both NK and T (mostly Th1) cells, but most murine experiments with FasL-deficient donor T cells suggested that FasL is a key effector molecule for causing GVHD but not GVL. However, one study found that FasL is required for $CD4^+$–mediated GVL against myeloid leukemia. By contrast, even though perforin-mediated CTL pathways are also used by T (mostly Th2) and NK cells, experimental data with perforin-deficient donor T cells demonstrated a loss of GVL with a diminution in the severity of GVHD. In some other experimental models, perforin was required only for GVL but not for GVHD. Recent data showed that TRAIL-mediated CTL had no effect on GVHD severity but was required for optimal GVL. Therefore strategies that increase donor T-cell TRAIL expression or enhance the susceptibility of tumors to TRAIL-mediated CTL (e.g., HDAC inhibitors) may promote a robust GVL effect without exacerbating GVHD. Thus a significant progress has been made in recent understanding of the CTL pathways used by donor T cells for GVL responses, but the role and context of use of these pathways by donor NK and NKT cells after allogeneic HCT are not known.

DONOR LEUKOCYTE INFUSIONS

Until recently, the evidence for an important GVL effect in clinical transplantation was strong but largely circumstantial. The use of DLI to treat relapses after allogeneic HCT has now provided direct evidence of the GVL effect. Kolb and colleagues first reported three patients with relapsed CML who achieved complete cytogenetic remission after treatment with IFN-α and DLI from the original donors. Subsequently, these findings have been confirmed in several reports. Two large retrospective studies of DLI have been reported from Europe and North America. Although the treatment protocols varied slightly among institutions, the results have been remarkably consistent. When results from these trials are combined, the complete remission rate for patients treated for relapsed CML is consistently 60% to 80%. In many patients with CML, the response to DLI is not immediate. The average time to obtain a molecular remission is between 4 and 6 months, but disease-free survival after DLI depends on the stage of CML. Complete cytogenetic and molecular responses are achieved in almost 80% of patients treated with either early relapse (cytogenetic or molecular) or hematologic relapse of chronic phase. Patients with more advanced CML (accelerated phase or blast crisis) are less likely to respond. Two recent analyses suggest that the outcome after unrelated DLI is similar to matched sibling DLI in CML patients.

DLI has also produced remissions in acute leukemias. Several retrospective studies have reported response rates in AML ranging from 20% to 65%. A prospective study of 65 patients with advanced myeloid leukemia who received cytarabine and G-CSF–primed DLI showed that 47% of the patients achieved complete remission, with an overall survival of 19% at 2 years. A recent European Blood and Marrow Transplantation (EBMT) analysis of DLI in patients with relapsed AML showed a response rate of 41%, which did not change if chemotherapy was used before DLI. In general, DLI produces lower response rates and higher relapse rates in patients with AML than in those with CML. Extramedullary relapses at multiple regions that are usually not considered sanctuary sites for leukemia have been observed after DLI.

Although GVL responses to ALL after allogeneic HCT have been noted, DLI for ALL has generally been ineffective. Reports both from Europe and the United States found little benefit for DLI in ALL patients. Furthermore, Ruggeri and others found that, following TCD haploidentical HCT where the donors had antirecipient NK cells, the probability of relapse was 85% for ALL in contrast with 0% for AML.

The experience with DLI for other hematologic malignancies such as non-Hodgkin lymphoma and multiple myeloma (MM) is much more limited. Case reports and small series demonstrate responses to DLI in patients with posttransplant relapses of low-grade lymphoma and CLL and also after low-intensity HCT. In MM, complete responses to DLI were observed in 25% of the patients in two small series. DLI has also been shown to induce complete remission in a majority of patients with posttransplant lymphoproliferative disorders (PTLDs) after allogeneic HCT. Viral infections may be treatable with DLI, and adoptive immune therapy with T cells specific for EBV and CMV have been shown to both treat and prevent these complications.

Complications of Donor Leukocyte Infusions

Adoptive immunotherapy with DLI causes significant morbidity. The major complications are myelosuppression and GVHD. Myelosuppression with anemia and/or thrombocytopenia and/or leucopenia and/or pancytopenia occurs in 34% of the patients. Marrow aplasia presumably results from the destruction of host leukemia cells before recovery of normal donor hematopoiesis. This idea is supported by the observation that patients treated with donor mononuclear cell infusions for cytogenetic or molecular relapse rarely experience pancytopenia. Occasionally, marrow aplasia has been persistent, although this toxicity has been successfully reversed with the infusion of additional donor stem cells in some patients. If pancytopenia is associated with chronic GVHD, then immunosuppression might be the most appropriate therapy. Acute GVHD and chronic GVHD have been the major direct complications from DLI. In retrospective and prospective studies, acute or chronic GVHD has been reported in 40% to 60% of evaluable patients. In most studies, GVHD correlates with GVL activity and response. In the North American analysis, more than 90% of complete responders developed acute GVHD, and 88% of responders developed chronic GVHD. Of 23 patients who did not experience GVHD, only 3 achieved a complete remission. In 92 patients who had no response, only 35% had acute GHVD and only 13% had chronic GVHD. In the EBMT analysis, 41% of DLI recipients developed grade II to IV acute GVHD. However, it should be noted that many patients who fail to respond to GVL induction will die shortly of progressive disease and may not survive long enough for GVHD to develop. This is particularly important for patients with acute leukemia. It is also important to emphasize that a number of complete responses were seen in patients without any sign of GVHD. The GVL effect in the absence of clinical GVHD provides important evidence for GVL activity separate from GVHD.

In general, GVHD that occurs after DLI has been mild to moderate and has been responsive to immunosuppressive therapy. This observation is important because the dose of T cells often administered with DLI may be 10- to 100-fold higher than the T-cell dose administered at the time of transplant, and DLI is given without additional immunosuppression. At the time of transplant, toxicity is unacceptable if immunosuppression is withheld or if a dose of donor T cells similar to that used for DLI is given (to augment GVL). This may be because the effects of GVHD are more tolerable when separated from the acute transplant toxicity. GVHD can be stimulated and exacerbated by the cytokine storm that may accompany transplantation. Tissue damage from the intensive conditioning regimen, infections, and other physiologic insults results in a cascade of events that ultimately augments the GVHD reaction. When GVHD is induced independently of other transplant related toxicity, it may be more manageable with appropriate immunosuppression. Nevertheless, in some cases DLI-induced GVHD may be quite severe; as shown in Table 109.2 , 20% to 35% of DLI recipients can be anticipated to develop grade III or IV acute GVHD. Furthermore, acute GVHD has contributed to death in almost 10% of patients. Chronic GVHD occurs in 30% to 60% of recipients of unmanipulated DLI.

It is notable that the clinical presentation of GVHD after DLI is somewhat different from that after myeloablative allogeneic HCT. For instance, the onset of GVHD may be later after DLI. The median time to onset of acute GVHD is approximately 32 to 42 days compared with a median time to onset of 16 to 20 days following myeloablative T cell–replete transplantation. Therefore, not only can the severity of GVHD be influenced by the use of intensive conditioning, but the tissue damage and inflammatory cytokine release may influence the pace of GVHD development as well. This possibility is supported by the finding that time to onset of acute GVHD is also delayed following reduced intensity transplantation. The target organs of acute GVHD following DLI are the same as those seen following HCT, but the clinical manifestations may differ. A hepatic variant of liver GVHD characterized by marked elevations of serum aminotransferase levels more than 10 times the upper limit of normal was observed in 11 of 73 (15%) patients who received DLI at Johns Hopkins University. Characteristic skin, liver, and intestinal acute GVHD manifestations can be seen following DLI, but their frequency and severity has not been well described. In a study of 81 patients who received DLI for relapse, mixed chimerism, or prophylaxis following reduced-intensity HCT, skin, liver, and intestinal GVHD developed in 26%, 8%, and 14%, respectively. Likewise, characteristic findings of chronic GVHD can be seen following DLI, and on occasion both acute and chronic GVHD can develop simultaneously following DLI.

In recent years, DLI has been used in the context of reduced-intensity allogeneic HCT. When conditioning is minimal and GVHD has not already occurred, DLI is often required to either reverse mixed chimerism or treat persistent disease. GVHD after DLI following nonmyeloablative setting develops 19% to 45% of the time, whereas chronic GVHD develops 28% to 34% of the time. In two studies of a combined 134 subjects who received DLI after reduced-intensity transplantation, 37 (28%) patients developed acute GVHD, 15 (11%) developed grade III or IV GVHD, and 8 (6%) died from GVHD. There was no statistically significant relationship between DLI dose and GVHD in either study. The clinical features of GVHD after DLI following reduced-intensity HCT are similar to the GVHD that occurs after DLI is used to treat relapse following myeloablative HCT. The similarity between GVHD after DLI in either setting suggests that the reduction of tissue damage associated with either no chemotherapy (as in DLI for relapse following prior myeloablative HCT) or reduced-dose chemotherapy (as in DLI after reduced-intensity HCT) may be an important common theme.

It is likely that effector cells responsible for the GVL and GVHD effects of HCT will similarly be responsible for the GVL effect associated with DLI, although this assumption has not been formally proven. The administration of select subsets of donor mononuclear cell fractions is the ideal setting in which to dissect the cellular mechanisms responsible for GVL induction, and strategies that delay the infusion of these various cellular subsets will help to define the mechanisms and enhance the efficacy of DLI.

FUTURE DIRECTIONS

Complications of HCT, particularly GVHD, remain major barriers to the wider application of allogeneic HCT for a variety of diseases. Recent advances in the biology of genetic polymorphisms, host microbiome, chemocytokine networks, several novel cellular subsets including Tregs, and the direct mediators of cellular cytotoxicity have led to improved understanding of this complex disease process. Animal studies show that modulation of several mediators of the complex GVHD cascade may be able to reduce the undesirable inflammatory aspects of GVHD while preserving the benefits of GVL. However, most of the laboratory observations remain to be studied in well-controlled clinical trials. Multiple cellular effectors may be involved in GVL, although donor T-cell recognition of host antigens is an important element of this process. Cellular immunotherapy such as DLI offers a strategy for separating GVHD and the GVL effect. Both experimental and clinical data suggest that posttransplantation cellular immunotherapy can be performed relatively safely and effectively, and optimization of patient selection, cell dose, and timing of administration may all serve to limit toxicity and enhance the potential GVL effects.

CHAPTER 110

SUPPORTIVE CARE FOR THE TRANSPLANT PATIENT

Abraham S. Kanate and Navneet S. Majhail

Although hematopoietic cell transplantation (HCT) is a therapeutic option for various hematological and non-hematological disorders, it can result in toxicities and complications, leading to significant treatment related morbidity and non-relapse mortality (NRM). Based on the temporal association from the date of HCT, these may be divided into early complications (within the first 3 months of HCT) or late complications (beyond 3 months of HCT), but can vary between patients based on comorbidities, type of HCT (autologous versus allogeneic), conditioning regimens and intensity, type and duration of immunosuppressant use, antimicrobial prophylaxis, and long-term post-transplant survivorship care (Fig. 110.1). By etiology post-HCT complications may also be classified as infectious, early non-infectious complications, late non-infectious complications, and graft-versus-host disease (GVHD) (Table 110.1). Identification of risk factors for complications allows the design of risk-specific treatment and supportive care plans that may reduce treatment-related morbidity and mortality.

INFECTIONS

Infections are common causes of NRM in HCT recipients and cause significant morbidity, in both the early and late transplant period (Table 110.2). Immune defects occurring in the post-transplant period can be divided into predictable phases based on time from transplant, with characteristic infections in each phase (see Fig. 110.1). Antimicrobial prophylaxis tailored to address the risk of specific infections are effective in decreasing the incidence of post-transplant infections (Table 110.3). Evidence-based guidelines for preventive strategies have been published and can be used as a reference for determining infection risk and assigning antimicrobial prophylaxis for an individual patient.[1,2]

Neutrophil engraftment (sustained absolute neutrophil count >500/μL) generally occurs within 10 to 14 days in autologous and 14 to 28 days in allogeneic HCT recipients. Allografts utilizing bone marrow or umbilical cord (UCB) as the graft source tend to engraft later compared to peripheral blood allografts. Importantly, 5% to 10% of allo-HCT recipients may have primary graft failure, causing prolonged neutropenia and transfusion dependence. Risk factors for infection during the neutropenic phase are disruption of mucocutaneous barriers and indwelling venous catheters. Bacterial infections can occur in ~30% of transplant recipients during this initial period and usually arise from normal flora of the skin (coagulase-negative *Staphylococcus*), oropharynx, and gastrointestinal tract (*Streptococcus viridans*, *Enterococcus* spp. and enteric gram-negative bacilli). Colonizing yeasts or molds may also cause systemic mycotic infections (usually *Candida* or *Aspergillus* spp.) in ~10% to 15% of patients due to neutropenia and disruption of normal host flora. Reactivation of herpes virus can occur in the absence of prophylaxis.

The predominant defect seen in the early to late post-engraftment period is impaired cellular and humoral immunity. This state of underlying severe immune dysfunction is enhanced and prolonged by acute and chronic GVHD needing corticosteroids and other immunosuppressive agents, sometimes lasting beyond 2 years of HCT. The incidence of late opportunistic infections is lower in autologous HCT recipients because of relatively faster immune reconstitution. Patients with chronic GVHD can be functionally asplenic and at risk of infections by encapsulated bacteria. In addition, chronic GVHD patients on long-term immunosuppression are susceptible to fungi (*Aspergillus* spp., *Candida* spp., and *Pneumocystis jiroveci*) and viruses (cytomegalovirus [CMV]) and varicella zoster virus [VZV]). Additional factors that can delay immune reconstitution include donor-recipient human-leukocyte antigen (HLA) disparity, T-cell depletion (either by graft manipulation or in vivo by use of antithymocyte globulin or post-transplant cyclophosphamide) and donor type (unrelated donor, haploidentical donor and UCB transplantation).[3] Recommended antimicrobial prophylaxis should continue beyond the initial post-transplant period, typically for at least 3 to 6 months after cessation of all immunosuppression, especially in those with chronic GVHD. Some centers use total T-cell (CD3+) and particularly CD4 cell levels as surrogate markers of T-cell immunity and to guide duration of antimicrobial prophylaxis. Supplemental intravenous immunoglobulin (IVIG) has been considered for patients with persistent hypogammaglobulinemia (IgG levels <400 mg/dL), but its prophylactic use is costly, does not prolong survival or prevent late infections and may impair humoral immune reconstitution. Patients with GVHD and those with indwelling venous access who undergo dental procedures should receive antibiotics for endocarditis prophylaxis. Published guidelines are available for recommendations on immunization of HCT recipients (Table 110.4).[1,4,5]

Owing to the shorter duration of neutropenia in reduced intensity/non-myeloablative allogeneic (RIC/NMA) HCT, the incidence of bacterial infections is usually lower. However, the degree and duration of lymphodepletion are comparable to myeloablative regimens and the risks of opportunistic infections such as pneumocystis pneumonia, invasive aspergillosis and CMV reactivation remain unchanged. Among UCB and haploidentical donor allo-HCT recipients, neutrophil engraftment and immune reconstitution can be delayed and a higher incidence of bacterial and viral infections in the early post-transplant period has been reported,[6,7] but does not affect overall mortality and NRM. Infections that are unique to the HCT recipients are discussed in further detail here.

Febrile Neutropenia

Fever is a common occurrence in the early post-transplantation neutropenic phase, although an infectious pathogen is identified in only ~50% of the patients. Fever may also be due to tissue inflammation (oropharyngeal or enteric mucositis), transfusions, or drug reactions. Bacterial infections due to aerobic bacteria such as *viridans* streptococci and enteric gram-negative bacilli are the primary concern during this period, although yeast infections are also a possible cause of febrile neutropenia. Prophylactic strategies including suppressive antimicrobials such as fluoroquinolones, and azoles are considered during this period.

At the onset of febrile neutropenia, empiric therapy with broad spectrum antibiotics is promptly started along with appropriate clinical and microbiologic evaluation. The choice of antibiotics depends on prior and current antibiotic usage, accounting for local resistance patterns. These recommendations are based on the available guidelines for the treatment of febrile neutropenia in cancer patients.[8] Among patients with persistent febrile neutropenia, that is fever without an identified focus that continues despite 3 to 5 days of appropriate broad-spectrum antibiotics, invasive fungal infections

should be considered. Initiating empiric antifungal therapy with mold-active agents such as posaconazole, voriconazole or amphotericin is appropriate at this stage. The choice of agent is dependent on prior exposure to anti-mold agents for prophylaxis where resistant species (e.g., zygomycetes) may emerge. Empiric mold specific therapy can be started earlier in patients who have experienced prolonged periods of neutropenia pre-HCT (e.g., patients with myelodysplastic syndromes [MDSs]). Repeated vigorous investigation to identify sources of infection (e.g., computed tomography [CT] scans of the chest and sinuses), is essential. Although administration of myeloid growth factors (granulocyte colony-stimulating factor [G-CSF] or granulocyte-macrophage colony-stimulating factor [GM-CSF]) reduces the duration of neutropenia and accelerates neutrophil engraftment, they have not demonstrated reductions in mortality from early post-transplant infections. Granulocyte infusions have rarely been used for life-threatening infections during the pre-engraftment phase. However, questionable efficacy in "real-world" scenarios and logistical challenges have resulted in this strategy falling out of favor.

Cytomegalovirus Infection

Epidemiology and Risk Factors

Despite the introduction of effective antiviral therapies, CMV reactivation and infection can be a major cause of morbidity and mortality in allogeneic HCT recipients.[9] The risk of CMV reactivation spans both the early and late transplant period, especially in patients with active GVHD requiring prolonged immunosuppression. Although the incidence of early CMV disease with organ involvement has declined to 3% to 6% with the use of empiric antiviral drug therapy directed by routine surveillance with CMV DNA polymerase chain reaction (PCR) or antigenemia testing (pre-emptive strategy), late onset CMV infection and organ disease remain significant clinical concerns.[9]

Seropositivity of the recipient is the most important risk factor for CMV infection in HCT recipients, and reactivation of latent virus is the most important mechanism resulting in CMV disease. CMV infections (<5%) in seronegative recipients are extremely rare

TABLE 110.1 Major Complications of Hematopoietic Cell Transplantation

Complication	Incidence
Infections	
Bacterial Infections	
Gram-positive bacteremia	20%–30%
Gram-negative bacteremia	5%–10%
Viral Infections	
Cytomegalovirus	5%–40% in high-risk patients[a]
Herpes simplex virus	5%–10% in seropositive patients
Varicella-zoster virus	10%–50% in seropositive patients
Respiratory viruses	10%–20%
Fungal Infections	
Candida	5%–10%
Aspergillus and other molds	5%–15%
Pneumocystis jirovecii	<1%
Other Infections	
Toxoplasma gondii	2%–7% in seropositive patients
Early Non-infectious Complications (0–3 months)	
Regimen-Related Toxicity	
Mucositis	60%–75%
Hemorrhagic cystitis	5%–10%
Veno-occlusive disease	5%–40%
Pneumonitis	10%–20%
Alveolar hemorrhage	5%–10%
Graft failure	2%–10%
Adverse drug reactions	Common
Late Non-infectious Complications (>3 months)	
Organ-Specific Late Effects	
Cataracts	25%–40%
Hypothyroidism	30%–50%
Sterility/hypogonadism	50%–90%
Growth disturbances	30%–50% in prepubertal children
Osteoporosis/avascular necrosis	5%–20%
Malignant relapse	Variable
Second cancers	2%–12%
Graft-Versus-Host Disease	
Acute	20%–50% with related, 40%–90% with unrelated donors, 20%–50% with UCB, 10%–20% with haplo
Chronic	20%–40% with related, 40%–70% with unrelated donors, 20%–40% with UCB, 10%–20% with haplo

[a] CMV-seropositive HCT recipients.

CMV, Cytomegalovirus; *HCT*, hematopoietic cell transplantation; *UCB*, umbilical cord.

and likely result from exogenous exposure (primary CMV infection). The use of a CMV-seronegative donor in a seropositive recipient carries the worst risk for reactivation and is associated with repeated infections and decreased survival. Other risk factors for CMV reactivation include use of an unrelated donor, UCB or haploidentical donor HCT, in vivo T-cell depletion, older recipient age, increasing donor-recipient HLA mismatch, acute and chronic GVHD, and the need for prolonged immunosuppression, especially with high-dose corticosteroids. CMV reactivation can occur in autologous HCT patients as well, especially in those with extensive lymphodepleting prior therapies (e.g., fludarabine) but the risk of CMV end-organ disease is rare. Significant debate and research have gone into the evaluation of the potential role of CMV reactivation in decreasing post-HCT risk of disease relapse. The largest published study to date, including more than 9000 patients, showed no benefit in relapse risk but a higher a risk of NRM with CMV reactivation.[10]

Clinical Presentation and Diagnosis

CMV infection is often identified as asymptomatic reactivation noted by screening antigenemia or DNA PCR testing. The organs that are usually affected by CMV disease include the lungs (pneumonitis) and the gut (enteritis). CMV retinitis, hepatitis and encephalitis are less common and are usually seen in late-onset, recurrent CMV infection. Indirect effects of CMV infection may include increased risks of secondary graft failure and bacterial and fungal superinfection. Preceding CMV viremia is a strong predictor of subsequent clinical disease. CMV pneumonitis develops in 60% of patients with untreated asymptomatic viremia, and conversely effective treatment of CMV viremia reduces the incidence of CMV pneumonitis.

The diagnosis of CMV can be made either by demonstration of characteristic cytopathic effects in tissue or using more sensitive molecular methods that detect viral protein or DNA. Commonly used molecular assays include CMV DNA detection methods, and the pp65 antigenemia assay. Detection of the CMV pp65 antigen in leukocytes has been a commonly used method for CMV surveillance after HCT but is ineffective during early post-HCT leukopenia. Direct detection of CMV DNA either by PCR or DNA hybrid capture assay is the most sensitive method to detect CMV viremia. Furthermore, plasma CMV DNA PCR can be a valuable tool to monitor CMV during periods of neutropenia when CMV antigenemia testing is unreliable. In addition, quantitative real-time PCR assays allow estimation of viral load which can assist in determining the need for therapy, risk of disease progression and in monitoring response to anti-CMV treatment. Viral cultures of urine, saliva, blood or bronchioalveolar lavage (BAL), using either rapid shell-vial or routine culture techniques, have limited clinical utility since they are less sensitive than antigen or DNA detection techniques and take much longer to report. Since asymptomatic viral shedding in the airways is common, CMV DNA detected in BAL should be carefully interpreted. Higher viral loads and pre-test probability of CMV pneumonitis in these patients increase the positive predictive value of these tests.[9]

Prevention and Treatment

For seronegative recipients, the use of seronegative donors and CMV-safe blood products is the mainstay of prevention of CMV disease (see box on Approach to Prevention and Treatment of CMV Infection). For high-risk patients (seropositive recipients), two general strategies can be utilized, both of which have been effective in reducing early CMV infection rates to less than 10%.[9] In the "pre-emptive therapy" strategy, patients are monitored periodically (usually weekly) by quantitative PCR with prompt treatment of early CMV viremia with ganciclovir, valganciclovir, or foscarnet before it can lead to clinical disease. In "prophylactic therapy" at-risk patients are treated with anti-viral prophylaxis. Earlier studies evaluating the use of prophylactic ganciclovir and foscarnet did reduce rates of CMV infection but did not result in improved survival and was offset by drug related toxicities such as myelosuppression and renal dysfunction.[9] The antiviral, letermovir was

TABLE 110.2 Common Infections in Hematopoietic Cell Transplant Recipients

Pathogen	Risk Period After HCT (Weeks)	Risk Factors	Common Clinical Syndromes	Treatment
Gram-positive cocci	1–4	Neutropenia Mucositis Central venous catheters Skin breakdown	Bacteremia	Antibiotics based on susceptibility testing
Enterobacteriaceae spp.	1–4	Neutropenia Skin breakdown GI mucosal breakdown	Bacteremia	Antibiotics based on susceptibility testing
Clostridoides difficile	1–8	Antibiotics	Colitis	Metronidazole Oral vancomycin
Encapsulated bacteria[a]	>12	Chronic GVHD Chronic immunosuppression	Sinusitis Pneumonia	Antibiotics based on susceptibility testing

Aspergillus spp.	1–4>8	HLA-disparity CMV infection Acute or chronic GVHD Chronic immunosuppression High-dose corticosteroids	Sinusitis Pulmonary nodules or infiltrates	Mold specific azoles Echinocandins Amphotericin
Pneumocystis jirovecii	>4	Chronic GVHD Chronic immunosuppression	Pneumonia	TMP-SMX Dapsone Pentamidine
CMV	>4	Recipient or donor seropositivity HLA-disparity Acute or chronic GVHD Chronic immunosuppression	Viremia Enteritis Interstitial pneumonitis	Ganciclovir Foscarnet Valganciclovir
HSV	1–4	Recipient seropositivity	Oro-pharyngeal Esophagitis	Acyclovir Valacyclovir Foscarnet
VZV	>4	Recipient seropositivity History of chickenpox HLA disparity Acute or chronic GVHD Chronic immunosuppression	Cutaneous Interstitial pneumonitis Hepatitis	Acyclovir Valacyclovir Foscarnet
EBV	>4	HLA disparity T-cell depletion	Viremia PTLD	Rituximab Reduce immunosuppression Virus-specific T cells Cytotoxic chemotherapy

[a] Includes *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*.
CMV, Cytomegalovirus; *EBV*, Epstein-Barr virus; *GI*, gastrointestinal tract; *GVHD*, graft-versus-host disease; *HCT*, hematopoietic cell transplantation; *HLA*, human leukocyte antigen; *HSV*, herpes simplex virus; *PTLD*, post-transplant lymphoproliferative disorder; *TMP-SMX*, trimethoprim-sulfamethoxazole.

studied in a phase III randomized trial versus placebo in CMV-seropositive allogeneic HCT recipients for 12 weeks post-transplant and resulted in reduced CMV infections and improved all-cause mortality at 24 weeks.[11] Letermovir should be considered in these patients. However, they do need additional acyclovir for prophylaxis against herpes simplex and varicella. Both approaches require aggressive surveillance to allow prompt detection of infection. Unlike ganciclovir, which is administered intravenously, its prodrug valganciclovir, has excellent oral bioavailability and is often used for prophylaxis and pre-emptive therapy of CMV infection among HCT recipients. Surveillance for CMV is continued weekly until at least day 100 post-transplant for high-risk patients and is continued longer in patients with chronic GVHD on high-dose immunosuppression. In patients receiving prophylactic letermovir,

TABLE 110.3 Recommended Antimicrobial Prophylaxis Against Common Infections

Pathogen	Preventing Early Disease (0–100 Days After HCT)	Preventing Late Disease (>100 Days After HCT)
Bacterial infections	Quinolone prophylaxis during period of neutropenia	Antibiotics against encapsulated bacteria (e.g., *Streptococcus pneumoniae*) in patients on chronic immunosuppression
CMV	Letermovir prophylaxis recommended[a] or pre-emptive treatment with ganciclovir or valganciclovir	Pre-emptive treatment with ganciclovir or valganciclovir
HSV	Acyclovir/valacyclovir in seropositive patients	Acyclovir/valacyclovir in patients with recurrent HSV infections
VZV	Acyclovir/valacyclovir	Acyclovir/valacyclovir
Yeast infections	Fluconazole	Fluconazole in patients on chronic immunosuppression
Mold infections	Anti-mold triazole (e.g., posaconazole) prophylaxis in patients with GVHD[b]	Anti-mold triazole (e.g., posaconazole) prophylaxis in patients with GVHD[b]
Pneumocystis jirovecii	Trimethoprim-sulfamethoxazole (preferred) or dapsone or pentamidine or atovaquone	Trimethoprim-sulfamethoxazole (preferred) or dapsone or pentamidine or atovaquone in patients on chronic immunosuppression

[a] CMV-seropositive HCT recipients.
[b] Limited data available. Prospective testing of voriconazole and posaconazole suggests possible benefit as prophylaxis. No impact on mold-related mortality.
CMV, Cytomegalovirus; *GVHD*, graft-versus-host disease; *HCT*, hematopoietic cell transplantation; *HSV*, herpes simplex virus.

continued monitoring after cessation of drug is recommended to detect rebound infections.

CMV disease, especially pneumonia, must be diagnosed and treated promptly as it is associated with high rates of mortality. The combined use of ganciclovir and IVIG has been the most successful treatment for CMV pneumonia, with resolution in 50% to 75% of non-ventilator dependent patients. Prolonged therapy (>2 months) with the combination is indicated because shorter treatment regimens have been associated with a recurrence of CMV pneumonia, and granulocyte colony stimulating factor (GCSF) often necessary to manage ganciclovir-induced myelosuppression. Foscarnet, cidofovir or the combination of intravenous ganciclovir with foscarnet can be considered as second line therapy and early studies have shown promising data with maribavir for resistant or refractory cytomegalovirus disease.[9] The antiviral management of CMV enteritis, hepatitis and retinitis is similar, although the use of IVIG in these settings is more controversial.

Although rare, rising CMV viral loads and worsening end-organ dysfunction despite optimal therapy, should raise the concern of CMV antiviral resistance. Ganciclovir resistance occurs due to mutations to human cytomegalovirus gene UL97 and ganciclovir, foscarnet and cidofovir resistance through UL54 mutations.[9] Adoptive cellular therapies, using approaches to enhance natural killer (NK) or more commonly infusing donor or third-party CMV-specific cytotoxic T-cells (CTLs) have been studied. CMV-specific CTLs have shown efficacy although third party cells may be hampered by low proliferative capacity and persistence.

TABLE 110.4 Recommended Vaccinations for Hematopoietic Cell Transplant Recipients

Vaccine[a]	Time Post-HCT to Initiate Vaccine (Months)	No. of Doses[b]
PCV	3–6	2–3[c]
Tetanus, diphtheria, acellular pertussis[d]	6–12	3
Haemophilus influenzae conjugate	6–12	3
Inactivated polio	6–12	3
Recombinant hepatitis B	6–12	3
Inactivated herpes zoster	6–12	2
Inactivated influenza	4–6	1–2 yearly[e]
Measles-mumps-rubella (live)	24	1–2[f]
Varicella zoster (live)[g]	24	1[f]

[a] Vaccinations are deferred in patients with chronic GVHD until discontinuation of immunosuppression.
[b] A minimum of 1-month interval between doses is suggested.
[c] Following the primary series of three PCV doses, a dose of the PPSV23 to broaden the immune response might be given. For patients with chronic GVHD who are likely to respond poorly to PPSV23, a fourth dose of the PCV should be considered instead of PPSV23.
[d] DTaP (diphtheria tetanus pertussis vaccine) is preferred; however, Tdap can be used if DTaP is not available.
[e] For children <9 years of age, two doses are recommended yearly between transplant and 9 years of age.
[f] Not recommended <24 months post-HCT, in patients with active GVHD and in patients on immune suppression. In children, two doses of MMR (mumps, measles, and rubella) are favored. Lower viral dose vaccines (varicella vaccine, live [varivax], not zoster vaccine, live [zostavax]) may be preferred as potentially safer.
[g] Inactivated herpes zoster preferred and administered earlier in the course.
GVHD, Graft-versus-host disease; *HCT*, hematopoietic cell transplant; *PCV*, pneumococcal conjugate; *PPSV23*, 23-valent polysaccharide pneumococcal vaccine.

APPROACH TO PREVENTION AND TREATMENT OF CYTOMEGALOVIRUS INFECTION

Prevention

1. Seronegative recipient: Choose seronegative donor when possible. Consider chemoprophylaxis is seropositive donor is considered. Transfuse only cytomegalovirus (CMV) safe blood products. Leukocyte depletion by filtration and blood from CMV-seronegative donors are clinically equivalent alternatives.
2. Seropositive recipients: Avoid seronegative donor when possible. Letermovir prophylaxis is recommended in this setting, considering improvement in 24-month all-cause mortality. Ganciclovir (or valganciclovir) is also effective but is myelosuppressive. Intensive surveillance and early pre-emptive therapy required if letermovir prophylaxis not possible.
3. All patients need periodic (weekly) monitoring for CMV DNA PCR for at least 12 weeks post-transplantation. Longer duration (beyond 12 weeks) surveillance is appropriate for allograft recipients with graft-versus-host disease (GVHD) and those previously on chemoprophylaxis to detect rebound.

Treatment

1. Asymptomatic infections: Ganciclovir or valganciclovir treatment of asymptomatic infection detected in blood or bronchioalveolar lavage (BAL), by either molecular detection or antigenic methods, is recommended to prevent the development of CMV pneumonia. Intensive induction treatment (2 weeks) followed by a maintenance phase of 5 days/week therapy for an additional 4–8 weeks is necessary.
2. CMV pneumonia: Ganciclovir in combination with immunoglobulin is recommended. This should be instituted promptly. Once the disease has progressed to cause respiratory failure and ventilator dependence, outcomes are bleak.
3. Foscarnet and cidofovir are alternatives to CMV disease that is resistant or refractory to ganciclovir.

Other Latent Viral Infections

Primary and reactivation of other herpes viruses can occur after transplantation. Herpes simplex virus (HSV) infection is uncommon with the routine use of acyclovir or valacyclovir prophylaxis in serologically positive patients. Albeit uncommon, acyclovir-resistant HSV infection may occur in patients given a low-dose or intermittent prophylaxis and recipients of T-cell depleted grafts. Foscarnet is the drug of choice for resistant disease with cidofovir reserved as an alternative agent. Varicella zoster reactivation can occur in 30% to 50% of HCT recipients with previous exposure to VZV and can be effectively prevented by acyclovir prophylaxis. Acyclovir prophylaxis is recommended for the first year after transplantation for VZV seropositive autologous and allogeneic HCT recipients, although patients with chronic GVHD on immunosuppression and patients on maintenance proteasome inhibitors will need extended prophylaxis.

Human polyomavirus type I, also known as BK virus, can cause hemorrhagic cystitis in the early post-transplant period. Urine PCR can identify BK virus and distinguish it from hemorrhagic cystitis caused by other infections (e.g., adenovirus) and urotoxic agents (e.g., cyclophosphamide). Lowering the immunosuppressive therapy, if possible, should be the first step. Quinolone antibiotics suppress BK virus replication in vivo and in vitro and may have a role as prophylaxis in patients at high risk for hemorrhagic cystitis. Intravesical or intravenous cidofovir has been used for the treatment of BK virus hemorrhagic cystitis.[1] BK-specific CTLs have been used in severe, progressive hemorrhagic cystitis. Rarely, BK virus encephalitis has been described post-allogeneic HCT. Another polyoma virus, John Cunningham (JC) virus, can reactivate in immunocompromised HCT recipients and cause progressive multifocal leukoencephalopathy, a fatal demyelinating disease of the central nervous system.

Human herpes virus 6 (HHV-6) can also reactivate from latency post-HCT, with incidence ranging from 20% to 60%, depending on donor type and graft source. Although reactivation is a common, routine surveillance is not recommended. Treatment with ganciclovir or foscarnet is recommended in symptomatic patients (headache, mental status changes, unexplained fever and/or rash, bone marrow suppression) with accompanying high viral load (>25,000 copies). Asymptomatic reactivation of HHV6 is common and is not associated with adverse post-HCT outcomes.[12]

Acquired Viral Infections

HCT recipients are prone to seasonal and community-acquired respiratory viral (CRV) infections including influenza, parainfluenza, and respiratory syncytial virus (RSV). Upper respiratory infections can rapidly progress to more serious lower respiratory infections in immunocompromised HCT recipients. It is of vital importance to promptly initiate appropriate diagnostic testing (e.g., nasopharyngeal swabs) to identify the virus if possible. Zanamivir or oseltamivir can be used as chemoprophylaxis for HCT recipients with known contact to a case, as well as for treatment of influenza. Aerosolized ribavirin may be considered in patients with RSV lower respiratory tract infection. Novel antivirals are needed to treat respiratory viral infections in HCT recipients. A novel inhaled antiviral, DAS181 (Fludase), cleaves sialic acid-containing receptors on the surface of host respiratory epithelial cells, thus preventing parainfluenza virus attachment to and infection of respiratory cells has shown some activity.

In 2020, a novel coronavirus (SARS-CoV-2) caused a global pandemic of COVID-19 infection characterized by a viral syndrome with a predominance of respiratory symptoms. At the time of writing this chapter, the epidemiology, risk factors, clinical presentation, and outcomes in HCT recipients were not well described. However, HCT recipients were anticipated to be at high-risk for getting infection and for developing more severe manifestations and adverse outcomes.[13] It is expected that this virus will continue in circulation for some time, and its impact and management in the transplant population will become clearer with increasing experience.

Fungal Infections

Invasive fungal infections are among the leading causes of morbidity and mortality in HCT recipients. Most fungal infections in this setting are caused by yeasts (*Candida* spp.) or molds (*Aspergillus* spp.).

Candida infections

Candida albicans has been the leading cause of yeast infections in HCT recipients, but the current widespread use of azole (e.g., fluconazole) prophylaxis in the early transplant period has led to the emergence of a variety of non-*albicans* species, such as *Candida tropicalis, Candida krusei*, and *Candida glabrata*, as important pathogens.[14] Yeasts are normal inhabitants of the skin, oral and gastrointestinal mucosa. Breakdown of mucosal surfaces due to radiation and chemotherapy, compounded by neutropenia in the pre-engraftment period, can greatly increase the risk of invasion and systemic infections. The presence of indwelling central venous catheters, parenteral nutrition and alteration of normal surface flora due to antibiotics are additional risk factors for *Candida* infections.[1]

Clinical manifestations can range from localized mucocutaneous to disseminated deep-tissue infection. A high index of suspicion is needed for the diagnosis of *Candida* infections, especially in patients with persistent febrile neutropenia since blood cultures are usually not very sensitive for isolation and identification of *Candida* spp. Oral and esophageal candidiasis frequently occurs in the early post-transplant period and should be treated aggressively as these can serve as portals for subsequent systemic infection. Venous catheter infections can be difficult to eradicate with antifungal agents alone and necessitate removal of the central line. Patients with candidemia are also at risk for endovascular infections such as endocarditis and thrombophlebitis. Hepatosplenic candidiasis is the most common manifestation of disseminated candidiasis although it is increasingly rare with widespread use of effective anti-candida azoles and echinocandins. Specific signs or symptoms related to organ involvement may be absent and the diagnosis frequently must be made by abdominal CT scan imaging.

Prophylaxis with fluconazole is recommended in the pre-engraftment and early post-engraftment period, especially among allogeneic HCT recipients.[1] In patients who are at high-risk for mold infections (e.g., severe GVHD), triazole antifungals such as posaconazole or voriconazole should be considered. Alternatively, caspofungin or micafungin can also be considered. In patients with severe GVHD, posaconazole prophylaxis compared to fluconazole was noted to be superior in preventing invasive aspergillosis and deaths due to fungal infections in a large phase III trial.[15] *C. krusei* and *C. glabrata* are intrinsically resistant to fluconazole and other antifungal agents (e.g., posaconazole, micafungin) should be preferred for prophylaxis in those colonized with fluconazole-resistant *Candida* species. Itraconazole is another active agent, but its use is limited by its tolerability and absorption. Cross-resistance to azoles can occur among *Candida* species. Anti-fungal agents for treatment of suspected or known invasive candidiasis include voriconazole or posaconazole, echinocandins or an amphotericin formulation, especially when infection occurs in the setting of ongoing fluconazole prophylaxis.

Aspergillus Infections

Most mold infections in HCT recipients are due to *Aspergillus fumigatus*, *Aspergillus flavus*, and *Aspergillus niger*, which gain entry through breakdown of mucosal surfaces or through the nasal passages and respiratory tract. Examples of non-Aspergillus molds causing infections in this setting include *Fusarium* species, zygomycetes and rarely *Scedosporium*. *Aspergillus* infections can occur early after HCT (during the neutropenic phase) or later, especially with prolonged immunosuppression associated with acute or chronic GVHD. Risk factors for *Aspergillus* infections include allogeneic HCT, prolonged neutropenia, concomitant CMV infection, and severe GVHD and high-dose steroids is a risk factor for invasive aspergillosis-associated mortality. Underlying primary hematologic diagnosis such as chronic granulomatous disease, aplastic anemia and MDS, which are associated with prolonged pre-transplant neutropenia also increase the risk. A prior history of *Aspergillus* infection has also been observed to be a risk factor for reactivation after HCT. As pointed out earlier, mold-active triazole prophylaxis should be considered in high-risk patients.

Aspergillus infection is intrinsically difficult to diagnose premortem. A high index of suspicion and an aggressive approach are required to establish diagnosis and initiate therapy. Since the nasal passages and tracheo-bronchial tree are the most common portals of entry for *Aspergillus* spp., these two sites are also the most common sites of infection. Sinusitis is frequently symptomatic and more advanced disease can be associated with erosion and necrosis of surrounding structures. Pulmonary manifestations typically include nodular infiltrates, usually distributed along the lung periphery, with pleuritic pain or cough as an initial symptom. Frank consolidation (with a halo sign on CT scan) or cavitary lesions can be seen in more advanced stages of pulmonary involvement. *Aspergillus* has angioinvasive properties and can present with hemoptysis or with intravascular dissemination to the skin or brain.

Blood cultures have a very low sensitivity in detecting *Aspergillus* and diagnosis relies on demonstration of typical fungal morphology on histopathology or on tests to detect fungal components or nucleic acids. Nasal and bronchial washings for *Aspergillus* may also not be sensitive and sinus or lung biopsy are often required to confirm diagnosis. The galactomannan assay is an enzyme-linked immunosorbent assay to detect the *Aspergillus* cell wall glycoprotein; it has a high specificity, but low sensitivity for diagnosing invasive aspergillosis and has not been reproducible. Molecular methods for diagnosis, including PCR for *Aspergillus* DNA, are also undergoing development. Assays to detect fungal cell wall component (1–3)-β-ᴅ-glucan are sensitive to detect most invasive fungal infections (except *Cryptococcus* and zygomycetes) but are not specific to *Aspergillus*. Often, tissue biopsy is needed to confirm the presence of *Aspergillus* in suspicious lesions. When biopsy is not possible, empiric therapy is recommended if clinical suspicion for mold infection is high.

The use of high-efficiency air filters has reduced the nosocomial acquisition of *Aspergillus*, at least during the early neutropenic phase. The optimal pharmacologic strategy for primary prophylaxis against aspergillosis is not well defined. Posaconazole is effective and recommended as prophylaxis in patients with severe GVHD. A large, randomized trial showed no difference in fungal-free survival between voriconazole and fluconazole prophylaxis in HCT recipients at low risk for disease progression or early HCT mortality, although there was a trend towards fewer *Aspergillus* infections and less empiric antifungal use in the voriconazole arm.[16] In patients with a previous history of invasive aspergillosis, secondary prophylaxis with a mold-specific azole (e.g., oral voriconazole or posaconazole), parenteral echinocandins, or an amphotericin preparation is recommended during the peri-transplant period and possibly for the duration of intensive immunosuppression. Similarly, in high-risk patients with persistent febrile neutropenia not responding to antibiotics, mold-directed therapy should be promptly initiated. Azoles and echinocandins have a more favorable side effect profile compared to amphotericin formulations. Patients with disease progressing on a single anti-mold drug might need combination therapy. The role of adjunctive measures such as cytokine growth factors, immunoglobulin infusion, or granulocyte transfusion remains undefined.

Pneumocystis jirovecii Pneumonia

Pneumonitis caused by *Pneumocystis jirovecii* (PJP) has a typical bilateral distribution with a "butterfly" pattern on chest radiograph and is clinically associated with dyspnea and significant hypoxemia. The risk of *Pneumocystis* pneumonia is effectively eliminated with routine use of prophylaxis with TMP-SMX (first choice), dapsone, atovaquone, or aerosolized pentamidine. For those prescribed PJP prophylaxis, compliance must be ensured before ruling it out as a possible etiology. Diagnostic confirmation requires cytologic evaluation of silver-stained preparations of BAL cells or sputum, although transbronchial lung biopsy may slightly increase the diagnostic yield of a bronchoscopy examination. Although not confirmatory, positive (1–3)-β-ᴅ-glucan assay can be a useful marker for PJP besides invasive fungal infections. *Pneumocystis* pneumonia is effectively treated with high dose TMP-SMX or parenteral pentamidine. PJP prophylaxis is recommended through the period of immunosuppression (6 to 12 months) or for the duration of any chronic GVHD therapy in allogeneic HCT recipients and up to 3 months for autologous HCT recipients.

EARLY NON-INFECTIOUS COMPLICATIONS

Chemotherapy and radiation are used as conditioning agents before transplantation for their antineoplastic and immunosuppressive effects. However, these regimens, especially myeloablative conditioning (MAC) can cause recipient tissue damage, resulting in significant morbidities. Early HCT-associated complications can frequently simulate infections or be compounded by concurrent infections. Additionally, delays in hematopoietic recovery can potentially hinder epithelial tissue repair and cause local microinvasive infections, thus exacerbating and prolonging the toxicities.

Graft Failure

Failure to establish hematologic engraftment (primary graft failure) and loss of an established graft (secondary graft failure) are serious complications of both autologous and allogeneic HCT. Delayed or poor graft function can exaggerate and prolong the risks of infection and increase the risk of peri-transplant mortality. Failure to engraft can occur if insufficient hematopoietic progenitors are infused. If bone marrow is used as the graft source, a minimum of ~2×10^4 colony-forming cells from marrow per kilogram (kg) recipient weight are needed to establish autologous engraftment. This is accomplished by infusing approximately 1×10^8 autologous marrow mononuclear cells/kg. Bone marrow is rarely used for autologous HCT. For bone marrow allografts, a minimum of 2×10^8 mononuclear cells/kg cell dose is recommended to ensure adequate hematopoietic recovery. In UCB transplants, a lower cell dose is usually sufficient to ensure hematopoietic recovery. It is recommended that a single UCB unit has a cell dose of greater than 2.5 to 3×10^7/kg mononuclear cells and when double UCB units are used, each unit should have greater than 1.5×10^7/kg mononuclear cells.[17]

Obtaining hematopoietic stem cells and progenitor cells from peripheral blood by apheresis instead of bone marrow harvest is widely prevalent, both for autologous and allogeneic HCT. For autologous transplantation, peripheral blood hematopoietic cell grafts are collected after mobilization of marrow-derived progenitors into the blood by cytokine (G-CSF or GM-CSF) therapy or during recovery from myelosuppressive chemotherapy, often in combination with growth factors. Hematopoietic cell content of blood or marrow grafts is assayed by quantitation of mononuclear cells expressing the hematopoietic progenitor-associated surface marker CD34. Peripheral graft mobilization can be further enriched using plerixafor, an inhibitor of CXCR4 that releases cells from the marrow. Allogeneic grafts are mobilized from healthy donors using growth factors alone, nearly exclusively using G-CSF, though clinical trials with plerixafor have been completed.

Graft failure is uncommon if 2×10^6 CD34+ cells/kg or more are utilized in autologous and allogeneic HCT. Mobilized peripheral blood derived hematopoietic cells yield satisfactory and more rapid trilineage hematopoietic recovery than marrow-derived grafts. Secondary graft failure is unlikely (<5%) after transplantation using peripheral blood hematopoietic cells. Recipient factors such as myelofibrosis and splenomegaly can impair hematopoietic recovery due to faulty homing of progenitor cells in the marrow microenvironment or sequestration of cells in the spleen, respectively. Graft failure or poor graft function can also be associated with the use of methotrexate, anti-thymocyte globulin (ATG), acyclovir, ganciclovir, trimethoprim-sulfamethoxazole (TMP-SMX), and mycophenolate mofetil (MMF) in the peri-transplant period. Post-transplant complications such as CMV, HHV-6 or fungal infections, and acute and chronic GVHD can also compromise successful hematopoietic function.

Allogeneic transplantation from a matched sibling donor at HLA-A, -B, and -DR loci are rarely (1% to 3%) associated with graft failure; however, the probability of graft failure increases with greater degrees of HLA incompatibility. In a matched unrelated donor (at HLA-A, -B, -C, and -DRB1) allo-HCT the rate of graft failure is less than 5% but is higher in mismatched donor HCT. Thus, the degree of HLA-match is a significant determinant to decrease the risk of graft failure. The presence of donor-specific antibodies (DSA) in the recipient against the donor HLA molecules is associated with increased risk of graft failure in the setting of a matched/mismatched unrelated donor, haploidentical donor and UCB transplantation. Major ABO incompatibility, inadequate immunosuppression, and reduced intensity conditioning are other risk factors for graft failure in allogeneic HCT. Evaluating donor chimerism by PCR amplification can distinguish between donor and recipient hematopoietic elements. Increasing recipient T-cell repertoire in the post-HCT setting is a risk factor for subsequent graft failure, especially after RIC/NMA conditioning. Early failure of an allogeneic graft can be due to the emergence of cytotoxic T-lymphocytes of host origin, presumably representing immune-mediated graft rejection. T-lymphocyte depletion (ex vivo or in vivo) of allografts for GVHD prophylaxis can potentially affect hematopoietic engraftment.

Neutrophil recovery time is usually delayed in patients receiving UCB grafts, compared to other sibling/unrelated allografts. Additionally, higher rates of graft rejection are noted with UCB grafts (5% to 15%). The risk of graft rejection can be minimized by improving the degree of HLA matching, ensuring adequate cell dose (>2.5 to 3×10^7/kg mononuclear cells for single UCB and greater than 1.5×10^7/kg mononuclear cells per unit for double UCB transplants) and avoiding units for which the recipient exhibits DSA. Ex vivo expansion is a potentially useful strategy to improve the infused cell dose in this setting. In recipients with anti-HLA antibodies, IVIG and anti-CD20 monoclonal antibodies have been used successfully to decrease antibody titer, although its clinical utility in this setting has not been well established. Growth factors such as GCSF and GM-CSF stimulate myelopoiesis and may be utilized prophylactically to ensure prompt neutrophil recovery in UCB and haploidentical donor transplantation. They are successful in improving myelopoiesis and neutrophil recovery in most cases of secondary graft failure and associated neutropenia. The use of recombinant human thrombopoietin and erythropoiesis stimulating agents to aid platelet and red cell recovery in this setting is controversial.

In the case of a failed autograft, infusion of previously harvested and frozen marrow or blood cells frequently reestablishes functional hematopoiesis. In allograft recipients with poor hematopoietic recovery, assessment of sorted T-cell chimerism can assist in distinguishing between immune mediated graft rejection (usually <5% donor derived T-cells detected) versus poor graft function in the setting of mixed chimerism.[18] It is vital to rule out other causes of secondary graft failure, such as infections and drug reactions. In the case of graft failure associated with low T-cell chimerism, a second infusion of donor marrow or cytokine-mobilized peripheral blood stem cells (stem cell boost) may allow successful engraftment. Due to the likelihood of immune-mediated rejection, immune/lymphodepleting reconditioning regimens are necessary prior to the stem cell boost to ensure adequate host immunosuppression. In recipients with mixed chimerism (5% to 95% donor T-cell) and poor graft function not responding to growth factors and tapering of immunosuppressive agents; donor lymphocyte infusions (DLI) may be considered to improve the donor chimerism to avoid impeding graft failure.[19] Stem cell boosts are readily available in the setting of related donors but can be more problematic in unrelated and UCB transplants. In case of graft rejection after UCB transplantation, a second transplant using cells from a different UCB or volunteer adult donor (related or unrelated) are possible options. Unfortunately, there is very little data on the outcomes of second allografts in these situations.

Veno-occlusive Disease

Hepatic veno-occlusive disease, also called sinusoidal obstruction syndrome (VOD/SOS), is a serious liver disorder characterized by jaundice, ascites, fluid retention and tender hepatomegaly, which complicates up to 5% to 50% of HCT.[20] The varying incidence is dependent on patient and transplant-related factors as well as stringency of diagnostic criteria used (see box on Veno-occlusive Disease). The primary initiating event is thought to be the conditioning agents (chemotherapy or radiation) causing sinusoidal endothelial injury, which leads to the release of fibronectin and factor VIII/von Willebrand factor, thus activating the coagulation cascade and formation of sinusoidal microthrombi and obstruction. This results in portal hypertension and centrilobular hepatocyte damage. Decreased plasma protein C levels, lower antithrombin III levels and elevated factor VIII and fibrinogen levels are usually noted. Cytokines such as tumor necrosis factor (TNF)-α and alterations in the levels of nitric oxide and matrix metalloproteinases may also have a role in its pathogenesis.

Risk factors associated with the development of VOD/SOS include patient-related factors such as age, performance score, underlying diagnosis, history of pre-transplant hepatitis or liver injury/radiation,

VENO-OCCLUSIVE DISEASE

Diagnostic Criteria for Veno-Occlusive Disease/Sinusoidal Obstruction Syndrome (VOD/SOS)

- Bilirubin ≥ 2 mg/dL before day 21 post-HCT and at least 2 of the following: (1) hepatomegaly or right upper quadrant pain, (2) ascites, or (3) weight gain >5% over baseline [Baltimore criteria].
- VOD/SOS is a clinical diagnosis; liver ultrasound with Doppler studies or liver biopsy can support or confirm the diagnosis.

Risk Factors

Pre-transplant Factors

- Prior hepatic inflammatory disease (e.g., hepatitis B/C, non-alcoholic steatohepatitis, alcoholic hepatitis)
- Prior hepatic fibrotic disease (e.g., cirrhosis)
- Extensive pre-HCT chemotherapy
- Prior exposure to gemtuzumab ozogamicin (AML) or inotuzumab ozogamicin (ALL)
- Prior liver irradiation

Transplant-Related Factors

- Conditioning regimen (e.g., myeloablative total body irradiation or alkylator (e.g., busulfan) conditioning
- Concomitant medications (e.g., sirolimus, itraconazole)

Prognostic Factors

Adverse prognostic factors include development of multi-organ failure (pulmonary, renal, encephalopathy), rapid increase in weight, rapid increase in bilirubin.

Prevention

- Ursodeoxycholic acid (prophylaxis)
- Defibrotide (investigational, phase III study was terminated early for lack of efficacy)
- Low-dose heparin and low molecular weight heparin (prophylaxis, not effective)

Treatment

Mild to moderate VOD/SOS: supportive care, aggressive fluid and weight management, avoid hepatotoxic agents. More 70% will have complete recovery.

Severe VOD/SOS: prompt therapy vital, mortality historically >80%. Initiate Defibrotide as soon as possible (only FDA approved therapy). Other measures such as tissue plasminogen activators and antithrombin III are investigational. Non-pharmacologic measures include supportive care, transjugular intrahepatic porto-systemic shunt (TIPS), and liver transplantation.

prior exposure to oxaliplatin, gemtuzumab ozogomicin or inotuzumab ozogomicin; transplant-related factors such as MAC regimens, higher dosage of total body irradiation (TBI) (>10 to 12 Gy), dose rate and increased busulfan dose, and concomitant use of other alkylators such as cyclophosphamide or melphalan. VOD may also be more frequent after mismatched related or unrelated donor transplantation. The use of sirolimus as GVHD prophylaxis in the context of busulfan containing MAC regimen can increase the risk. An online risk calculator is available to calculate the risk of developing VOD/SOS and may direct careful monitoring and early initiation of therapy (https://www.cibmtr.org/ReferenceCenter/Statistical/Tools/Pages/VOD.aspx).

The classical signs and symptoms of VOD are noted within 3 weeks after allo-HCT and two diagnostic systems have traditionally been used (1) modified Seattle criteria: bilirubin greater than 2 mg/dL, hepatomegaly, and greater than 2% to 5% weight gain (>2 parameters required) or (2) Baltimore criteria: bilirubin ≥2 mg/dL plus at least 2 of: hepatomegaly, ascites, ≥5% weight gain.[20,21] However, late-onset VOD/SOS and differences in clinical presentation among children are now recognized and are taken into account in revised criteria.[22] Progressive and severe VOD can be devastating, presenting renal and pulmonary complications, multi-organ failure, encephalopathy, and death. Early recognition and diagnosis of VOD/SOS has important clinical ramifications and cannot be over emphasized. It is imperative that the patient be evaluated carefully to rule out other causes of hyperbilirubinemia and weight gain (e.g., drugs, hepatitis, capillary leak, cardiac failure, volume overload). Although the gold standard for confirming the diagnosis is a hepatic biopsy, it may be challenging and associated with high risk of hemorrhage. Percutaneous or transabdominal needle biopsy in patients with thrombocytopenia and coagulopathy is not recommended. Transvenous biopsies may provide histologic material for diagnosis and may allow determination of hepatic wedge pressure product (>10 mm is associated with VOD), but the risk of bleeding should be considered. Ultrasonographic Doppler flow studies demonstrating reversal of portal flow or a higher portal vein resistive index may aid in the diagnosis. The diagnosis is almost always based on clinical parameters and hence a high index of suspicion must be maintained in at-risk patients for the early diagnosis and prompt initiation of therapy. Based on clinical parameters such as degree of hyperbilirubinemia, weight gain, other-organ dysfunction, VOD is graded as mild, moderate, and severe. Severe VOD is associated with very high mortality (>80%).

The most important factor in preventing VOD/SOS is probably calculating the risk score, which allows for careful patient selection and potentially modifying transplant-related factors to lessen the risk of subsequent VOD/SOS (e.g., RIC/NMA conditioning may be considered for a younger patient with prior hepatitis and exposure to gemtuzumab). Limited understanding of the cellular and microvascular pathophysiology of VOD/SOS has historically confounded development of more rational approaches to its prevention. Preventive strategies such as low-dose heparin, prostaglandin E, pentoxifylline (a TNF-α blocking agent), or ursodiol, have been studied although none has proved effective in prospective trials. Nevertheless, ursodiol prophylaxis is common in many centers due to its favorable safety profile and potential impact on liver toxicities and possibly survival.[23] Defibrotide (see below) has been evaluated as preventive strategy in prospective studies with promising results, especially in pediatric population.[24] However, a phase III trial stopped enrollment early based on interim analysis concluding that it was unlikely to meet primary objectives. For the treatment of VOD/SOS several pharmacologic and invasive measures have been studied with mixed results; recombinant tissue plasminogen factor (variable efficacy, risk of bleeding), diuretics (for fluid management), prostaglandins, transjugular intrahepatic portosystemic shunts (TIPS—limited and transient efficacy). Defibrotide, a single-stranded polyribonucleotide of porcine origin with probable anti-inflammatory, anti-thrombotic and anti-ischemic properties (exact mechanism of action remains unknown), showed favorable responses with 30% to 70% of patients with severe VOD/SOS achieving complete remission and noted improvement in survival compared to historical controls.[24] Defibrotide received Food and Drug Administration (FDA) approval based on the open label, phase III trial in patients with severe VOD/SOS defined by the Baltimore criteria plus renal/pulmonary dysfunction by day +28 and noted improved remission of VOD/SOS and day +100 survival rates, compared to historical controls.[25] It is recommended that defibrotide (6.25 mg/kg intravenously every 6 hours for at least 21 days) be promptly initiated in patients meeting diagnostic criteria, as delays in initiation of therapy can be potentially fatal.

Interstitial Pneumonitis

Pulmonary complications in the aftermath of HCT is common and ranges from atelectasis, volume overload, transfusion related pulmonary complications, engraftment reaction, bacterial pneumonia, interstitial pneumonitis (IP) and GVHD, spanning the early and late transplant period. IP is a frequent and potentially fatal complication that can affect up to 35% of recipients, especially allogeneic HCT. It is notably less common after autologous HCT. Although advances in supportive care and RIC/NMA have improved outcomes, it remains a cause for significant post-transplant morbidity. It is characterized by diffuse, interstitial inflammation of non-bacterial etiology accompanied by hypoxemia, dyspnea, and non-productive cough, and is associated with fever. Risk factors associated with the development of IP include the use of methotrexate for GVHD prophylaxis rather than cyclosporine, older age, severe early onset GVHD, time from diagnosis to HCT of >6 months, poor performance status and higher dose rate of irradiation during conditioning (>4 cGy/min). In one study, the risk of IP was 8% when none of these risk factors were present, compared to 94% when all six factors were present.[26] The clinical course of IP can be catastrophic, manifesting with rapidly progressive tachypnea, hypoxemia and hemodynamic compromise. Therefore, therapeutic interventions, often empiric based on clinical features, must occur before diagnostic tests can definitively confirm the diagnosis.

Infectious Causes of Interstitial Pneumonitis

Infections are the most common cause of IP in HCT recipients. Cytomegalovirus and *Aspergillus* are common infectious etiologies of IP and have been discussed in detail earlier in this chapter. Other important, uncommon infections to consider include *P. jirovecii* and RSV and similar, seasonal respiratory viruses. Clinical presentation and management of respiratory infections has been discussed in the infectious complications section above.

Non-infectious Causes of Interstitial Pneumonitis

Idiopathic Pulmonary Syndrome

Idiopathic pulmonary syndrome (IPS) is a serious complication characterized by IP that occurs in about 10% of HCT recipients, usually within the early post-transplant period (median time 2 to 4 weeks) and is indeed a diagnosis of exclusion after ruling out other known etiologies. Risk factors for IPS include older age, extensive prior chemotherapy, MAC regimens with high-dose cyclophosphamide and TBI (higher total dose and dose rate), blood transfusions, methotrexate for GVHD prophylaxis and active GVHD. It is thought that conditioning regimen and intensity plays a vital role in the pathophysiology of IPS by inciting pulmonary epithelial damage and subsequent macrophage and lymphocyte mediated immune response. Alveolar damage presenting as multilobar opacities on imaging, increased alveolar-arterial oxygen gradient, hypoxemia and exclusion of other causative factors are necessary to establish diagnosis. The management of IPS largely revolves around supportive care. High-dose glucocorticoids (>1 mg/kg) are often administered but their efficacy is not well established and progressive IPS carries a mortality risk of nearly 90%. Given the observation that inflammatory cytokines such as interleukin-1, -6, -8, and TNF-α, have been implicated in IPS, etanercept, a TNF-α binding protein has been evaluated in this setting. In a small series, etanercept with glucocorticoids resulted in clinical response but did not seem to improve survival outcomes. A phase III randomized trial comparing etanercept/placebo with glucocorticoids closed early due to poor accrual and did not show any clear benefit with etanercept over placebo.[27]

Diffuse Alveolar Hemorrhage

Diffuse alveolar hemorrhage (DAH) is a clinical syndrome of acute onset characterized by diffuse pulmonary infiltrates on imaging and the diagnosis is usually established by bronchoscopy showing progressively bloody fluid on sequential lavage.[28] Onset typically occurs within 3 months of HCT and presenting symptoms include dyspnea, hypoxia and cough, although late-onset alveolar hemorrhage has also been described. Alveolar hemorrhage may occur in the setting of lung infections or accelerated GVHD where, apart from supportive measures, treatment should be targeted at the underlying etiology. When no discernible etiology is identified, DAH represents a spectrum of non-infectious pulmonary complications which include IPS. Interestingly, DAH can occur after both autologous and allogeneic HCT, older age, and underlying GVHD are risk factors. Its pathogenesis remains poorly described, but likely is a result of a complex interactions, including alveolar injury from radiation and chemotherapy, inflammatory damage due to neutrophils and cytokines, and underlying infections. DAH can rapidly evolve into severe respiratory failure with mortality rates of greater than 70%. The mainstay of therapy includes prompt management of underlying etiology (e.g., infection or GVHD), correction of any coagulopathy, and aggressive ventilatory support. For DAH, high-dose corticosteroids remain the mainstay of therapy in most centers, although efficacy data are scant. Small case series have reported the successful use of recombinant factor VIIa and aminocaproic acid, but their efficacy needs to be confirmed in clinical trials and prothrombotic risks should carefully be counter balanced.

Other Complications

The early post-transplant period is invariably characterized by some degree of cytopenias needing platelet and red cell transfusion support, although this may be less pronounced after NMA/RIC conditioning. Judicious use of blood products is suggested for carefully balancing the benefits versus risks. Bleeding diathesis due to severe thrombocytopenia and coagulopathy resulting from vitamin K deficiency or infectious complications should be monitored. Transplant-related thrombotic microangiopathy (TMA) is a unique disorder typically seen in MAC allogeneic-HCT recipients taking tacrolimus and/or sirolimus for GVHD prophylaxis and is characterized by complement mediated injury causing microangiopathy, intravascular hemolysis, renal insufficiency, and neurological dysfunction. Management is supportive and using alternative therapy for GVHD prevention should be considered. Observational studies suggest that complement blockade with eculizumab may be an effective strategy in patients with end organ dysfunction and may lead to improved survival compared to historical controls. Gastrointestinal toxicities including oral mucositis, nausea/vomiting, diarrhea, and enterocolitis are commonly seen in the pre-engraftment phase and are usually related to conditioning toxicity and cytopenias. Treatment strategies mostly rely on supportive care, pain and symptom management and antimicrobials. For oral mucositis cryotherapy during MAC (e.g., radiation, melphalan) is commonly employed. Prophylaxis with palifermin (recombinant human keratinocyte growth factor) in patients undergoing high-dose conditioning has shown modest benefits. Deconditioning, functional incapacitation, nutritional deficiencies, and psychosocial turmoil are common during the transplant period and require the treatment team to be cognizant and responsive to the patient's individual needs in a multidisciplinary fashion.

LATE NON-INFECTIOUS COMPLICATIONS

Transplantation techniques and supportive care improvements have not only resulted in increased use of transplantation as a therapeutic strategy but have led to improvements in outcomes and long-term survival. The biggest challenge to long-term survival after HCT is relapse of the primary disease, and for recipients who remain disease-free through 2 to 5 years post-transplantation, the probability of survival over the next 10 to 20 years is greater than 80%.[23,29] However, survivors remain at considerable risk for late transplant-associated complications, which can include organ specific dysfunction, second cancers, infections due to ongoing immunodeficiency, and functional and psycho-social impairments and changes in quality of life (QOL). Among 5-year post-HCT survivors, 45% and 79% of autologous and allogeneic HCT recipients develop at least one late complication, respectively. Over a quarter of the allogeneic HCT patients may have >3 late effects. Unfortunately, transplant survivors appear to have higher risk of pulmonary complications, infections, hospitalization and all-cause mortality compared to their age-matched peers in the general population.[30] It is of paramount importance that physicians and other healthcare providers caring for transplant recipients be familiar with published guidelines for screening and prevention of late effects in HCT survivors.[4] Additionally, it is also important to follow general population guidelines for the screening and prevention of cancers, as well as chronic diseases and health maintenance.

The development of late effects is dependent on a myriad of patient-related (age, pre-HCT comorbidities and performance scores, existing lifestyle, underlying disease and therapies received), transplant-related (allogeneic HCT, conditioning intensity, radiation) and the presence of early post-transplant complications. Allogeneic HCT recipients who develop GVHD require long-term, and sometimes life-long immunosuppression. This can significantly affect their overall functional status and QoL, as well as increase susceptibility to adverse effects to drugs, infections, and second malignancies.

Organ-Specific Late Effects

Although any organ system can be involved, certain organs have a greater predilection for late-onset post-transplant complications (Table 110.5).[31] Dedicated long-term follow-up clinics and survivorship plans that monitor and screen patients for late complications per established guidelines are ideal (see Table 110.5). Early identification and management of late toxicities can potentially circumvent debilitating morbidities and mortality related to end-organ dysfunction. Late pulmonary complications (besides infections) including bronchiolitis obliterans and pulmonary hypertension negatively impact mortality. Cataracts develop in more than one-third of patients by 5-years post transplantation and are worsened by being on glucocorticoids, often requiring surgical therapy. Hypothyroidism can be seen in ~50% and hypogonadism in ~90% of HCT survivors. The majority of HCT survivors become permanently sterile, although HCT without TBI and use of RIC/NMA can be fertility-sparing. Prepubertal children may retain fertility, although secondary sexual development is often delayed. Up to 50% of children undergoing HCT also develop growth retardation. Musculoskeletal complications including osteoporosis and avascular necrosis can be particularly debilitating. An increased incidence of cardiovascular events and diabetes has also been reported. The risk for most organ-specific late complications continues to increase with time and continued surveillance for these problems are indicated in all HCT survivors.

Second Cancers

Secondary malignancies are rare but devastating complications of HCT. They account for 5% to 10% of deaths among survivors beyond 2 years after HCT. These include (1) post-transplant lymphoproliferative disorders (PTLD), (2) myelodysplasia and other hematologic malignancies, and (3) solid malignancies.[32]

PTLD comprises of a heterogeneous group of lymphoid proliferations, primarily involving B-lymphocytes that develop as a result of uncontrolled Epstein-Barr virus (EBV) infection and is usually donor-derived. They occur almost exclusively in allogeneic HCT recipients,

TABLE 110.5 Selected Late Complications of Hematopoietic Cell Transplantation

Complication	Risk Factors	Monitoring and Prevention
Endocrine		
Hypothyroidism	TBI/radiation	Assessment of thyroid and gonadal function at 6-months and annually thereafter
Hypogonadism	Chronic GVHD	
Growth retardation	Chemotherapy	
Ocular		
Cataracts	TBI/radiation	Ophthalmology evaluation at 6-months and annually thereafter
Keratoconjunctivitis sicca	Corticosteroids	
	Chronic GVHD	
Oral		
Dental caries	TBI/radiation	Dental evaluation, at 6-months and annually Thereafter
Dry mouth	Chronic GVHD	
Cardiovascular		
Coronary artery disease	TBI/radiation	Risk factor modification (monitor and manage hypertension, lipid panel, diabetes)
Cerebrovascular disease	Chemotherapy	Periodic clinical evaluation
Respiratory		
Bronchiolitis obliterans	TBI/radiation	Smoking cessation, clinical evaluation
Interstitial pneumonitis	Chronic GVHD	Pulmonary function tests, at 6-months and annually thereafter
	Infections	
Hepatic		
Cirrhosis	Hepatitis B or C	Periodic liver function tests
Iron overload	Transfusions	Serum ferritin level (at 1-year and as indicated)
Renal		
Nephropathy	TBI/radiation	Monitor renal parameters
	Chemotherapy	Monitor urine protein (annually)
	Cyclosporine	Control hypertension
Skeletal		
Osteoporosis	TBI/radiation	Periodic bone densitometry
Avascular necrosis	Corticosteroids	Imaging as indicated
Second cancers	TBI/radiation	Cancer screening as recommended
	Chemotherapy	
	Chronic GVHD	

GVHD, Graft-versus-host disease; *HLA*, human leukocyte antigen; *PCP*, *Pneumocystis carinii* pneumonia.

with an overall incidence rate of 1% to 2%. More than 80% of PTLD are diagnosed in the first year, although late occurrences have been described. Since T-lymphocytes play an important role in preventing proliferation of EBV-infected B-lymphocytes, removal of T-cells from the hematopoietic graft source (ex vivo or in vivo) is a major risk factor for PTLD. A greater degree of immunosuppression, usually noted in unrelated or mismatched allografts, the use of antithymocyte globulin or post-transplant cyclophosphamide, GVHD, all increase the risk for PTLD. Risk of PTLD is higher when EBV-seronegative patients receive EBV-seropositive allograft.

Clinical presentation of PTLD can be variable with patients presenting with constitutional symptoms, lymphadenopathy and end-organ dysfunction. Diagnosis usually requires histopathological confirmation. PTLD is classified as (1) early lesions (polyclonal), (2) polymorphic (polyclonal and monoclonal not meeting criteria for B-cell or NK/T-cell lymphoma), (3) monomorphic (monoclonal, meeting criteria for B-cell or NK/T-cell lymphoma), and (4) Hodgkin lymphoma-like. Treatment for early lesions and polymorphic-PTLD usually constitutes withdrawal of immunosuppression as tolerated and anti-CD20 monoclonal antibody such as rituximab. For monomorphic and Hodgkin lymphoma-like PTLD, combination chemotherapy ± rituximab (based on CD20 status) is necessary. Most transplant centers monitor for EBV viremia by quantitative PCR and consider pre-emptive therapy with rituximab (thus depleting the B-cells where EBV resides and replicates). Since PTLD can be associated with considerable morbidity and mortality, active surveillance and pre-emptive therapy is recommended for high-risk patients. EBV-specific cytotoxic lymphocytes have been shown to be efficacious in the treatment of refractory PTLD and clinical trials testing this approach in a multi-center setting are ongoing.

Secondary MDS and acute myeloid leukemia (AML) is seen in 5% to 5% of autologous HCT recipients, but is rare among allogeneic HCT patients, and has a latency period ranging between 3 and 5 years post-transplant.[32] Cytogenetic evaluation by fluorescent in-situ hybridization/karyotype and mutation analysis by next generation sequencing (NGS) may reveal characteristic chromosomal aberrations of therapy-related MDS/AML. Risk factors include older age, prior therapies (especially alkylators, topoisomerase inhibitors etc.) and conditioning regimens (e.g., irradiation). Overall outcomes are poor and long-term survival is less than 20% even with an allogeneic HCT.

Secondary solid cancers have a latency period of 3 to 5 years following HCT and the risk of incidence continues to rise with time and is higher than their age- and gender-matched peers in the general population. The cumulative incidence ranges from 1% to 2% at 5 years, 2% to 6% at 10 years, and 4% to 15% at 15 years post-transplantation.[32] Younger age at transplantation, prior therapy including immunomodulator therapy for myeloma, use of TBI and chronic GVHD are important risk factors for solid cancers. Solid cancers at a variety of sites have been reported, including cancers of the head and neck, breast, skin, liver, brain and nervous system, thyroid, and bone and connective tissue. Counseling regarding maintaining a healthy life style, smoking cessation, skin protection, and lifelong cancer screening is recommended for all HCT survivors according to established guidelines specific to transplant survivors and general population (Table 110.6).[4,33]

Quality of Life After Transplantation

Despite the significant early morbidities associated with HCT, most survivors attain high levels of physical and psychological QOL and return to full-time employment by 3 to 5 years post-transplant. Unfortunately, about 20% to 40% of long-term survivors carry the burden of therapy received and endure physical, functional, psychological, cognitive, sexual, and social impairments years after transplantation. The major risk factors for poor QOL are older age and advanced disease at transplantation, chronic GVHD, late complications of HCT described above and other medical problems. The patient's own personal and cultural background and expectations affect perceptions of QOL. Although chronic GVHD is a strong predictor of poor QOL, the overall health and functional status improves with resolution of GVHD and eventually reaches a level comparable to that seen in patients with no history of chronic GVHD. Gender-specific differences in QOL have also been observed, with females more likely to report impairments in psychological and sexual domains. Cognitive deficits, particularly involving executive function, memory, and motor skills, have been reported in 30% to 60%

TABLE 110.6 Screening Guidelines for Common Cancers After Hematopoietic Cell Transplantation

Site	Screening Recommendations[a]
Breast	Annual mammogram from age 40–45; for women receiving >800 cGy chest radiation screening to begin at age 25 or 8 years after radiation, whichever is later
Cervix	Start at age 21; Pap test every 3 years for ages 21–29; co-testing (Pap + HPV test) for ages 30–65
Colorectal	Start at age 45; stool-based tests (immunohistochemical, DNA) annually or direct visualization (e.g., colonoscopy every 10 years); certain high-risk groups (e.g., patients with inflammatory bowel disease) may need earlier initiation and more frequent screening
Lung	Imaging as clinically indicated; for high-risk patients between the ages 55 and 75 low-dose CT scan as per guidelines
Oral	Routine oral cavity exam
Thyroid	Annual TSH and thyroid exam; imaging as indicated
Skin	Annual skin checks

[a] Recommendations are based on published guidelines specific to HCT recipients and American Cancer Society recommendations for the general public.

of HCT survivors. The risk of developing these neuropsychological sequelae is increased in patients receiving transplantation at an older age, and with the use of irradiation based conditioning regimens and cyclosporine. Survivorship plans that incorporate periodic QOL-questionnaires are important for early identification and mitigation of QOL issues. A structured survivorship clinic and multi-disciplinary approach involving supportive care services, onco-psychiatry, and physical and mental rehabilitation are increasingly being employed and are recommended. Frailty and geriatric assessments prior to HCT and their impact on transplant outcomes, including QOL measures, are areas of active research.

GRAFT-VERSUS-HOST DISEASE

GVHD is a multisystem, clinicopathologic syndrome of donor-derived lymphocyte-mediated alloreactivity that commonly occurs as a complication of allogeneic HCT and leads to significant morbidity and mortality. It is usually classified as acute or chronic GVHD. Acute GVHD is further classified as classic acute GVHD (onset ≤100 days) and persistent, recurrent or late-onset acute GVHD (onset >100 days). In the absence of clinical features characteristic of acute GVHD, chronic GVHD is called classic chronic GVHD. When features of both acute and chronic GVHD appear together, it is classified as overlap syndrome, based upon a consensus conference on proposed definitions.[34,35]

Current understanding of the pathogenesis of GVHD suggests that alloreactive donor T-lymphocytes recognize histocompatibility antigens on host cells and initiate secondary inflammatory injury, leading to the clinical symptoms of GVHD. Acute GVHD is indeed driven by donor T-lymphocytes and inflammatory cytokines resulting in tissue destruction, whereas chronic GVHD is more complex and involves interactions between host immune system, autoreactivity, loss of immune tolerance and donor-derived dysregulated T- and B-lymphocytes.[36] The alloreactive response can be initiated or accelerated by conditioning regimen–induced tissue injury with release of proinflammatory cytokines, primarily interleukin (IL)-1 and TNF-α. GVHD is more frequent and more severe in recipients of partially matched or HLA-incompatible transplants, suggesting that major histocompatibility complex encoded molecules may be the prime antigenic targets initiating the alloreactive T-cell response. Minor histocompatibility antigens also play an important role in its pathogenesis. Activated donor derived T-cells produce IL-2 and interferon-γ, expand, and differentiate into effector cells and recruit mononuclear phagocytes and neutrophils that ultimately yield host tissue destruction, primarily through apoptosis. T-cell depletion of the graft (ex vivo or in vivo) reduces the risk of acute and chronic GVHD, albeit at the cost of increasing risks of disease relapse due to blunting of the graft-versus-tumor response.

Acute Graft-Versus-Host Disease

Risk Factors and Clinical Features

Published reports suggest that 10% to 50% of patients receiving HLA-identical sibling-donor develop acute GVHD. It is more common after unrelated donor and mismatched allografts. Donor-recipient HLA disparity is the most important risk factor for acute GVHD. Additional risk factors include increasing recipient and donor age, use of alloimmunized donors such as parous women, and HCT from unrelated instead of sibling donors. Among recipients of UCB, acute GVHD occurs in 20% to 60% of patients. Haploidentical donor transplantation is also a risk factor for acute GVHD, although it is partially reversed with the current strategy of post-transplant cyclophosphamide for GVHD prevention.

The skin, liver, and gastrointestinal tract are the most common sites of acute GVHD. Skin involvement is characterized by a maculopapular rash that, when severe, can lead to bullae formation and resemble toxic epidermal necrolysis. Hepatic involvement manifests as cholestatic jaundice with marked elevation of serum bilirubin and alkaline phosphatase, but usually only mild transaminase alterations. In the intestine, upper gastrointestinal tract GVHD can produce nausea, vomiting and anorexia, whereas small bowel and colon GVHD produces large volume secretory diarrhea. Acute GVHD is graded according to organs involved (skin, liver or gastrointestinal tract) and the extent (Stage) of each organ involvement (Table 110.7).[34] The diagnosis is clinical but frequently requires histologic confirmation to distinguish it from other frequent toxicities in the early post-transplantation period (e.g., hypersensitivity drug rash, drug-induced cholestasis, VOD/SOS, or infectious enteritis). The histologic hallmark of acute GVHD is apoptosis of the proliferative and regenerative cell layer of the epidermis, intestinal or biliary epithelium. Plasma biomarkers (ST2, REG3alpha, TNFR1) in patients with acute GVHD have been used to establish a prognostic algorithm that can predict response to therapy and NRM at 6 months.[37] The utility of implementing these biomarkers in routine clinical practice is an area of ongoing research.

Prophylaxis of Graft-Versus-Host Disease

The most effective techniques for GVHD prevention have involved ex vivo depletion of donor T-lymphocytes, most often coupling immunologic recognition (monoclonal anti-T cell antibodies) with depletion techniques (immunomagnetic beads, complement cytotoxicity or toxin immunoconjugates). Although vigorous T-cell depletion prevents acute GVHD, it also increases the risk of graft failure and relapse of primary malignancy after transplantation.

Pharmacologic immunosuppression and in vivo T-cell depletion administered in the early peri-transplant period prevent or blunt the initiating T-cell recognition and proliferative response that triggers GVHD and can allow development of immune system tolerance without impeding lymphohematopoietic recovery and donor chimerism. Methotrexate, corticosteroids, antithymocyte globulin, cyclosporine, tacrolimus, mycophenolate, and sirolimus have been used for prophylaxis of GVHD and have successfully reduced both the frequency and the severity of clinical GVHD. Despite the potential role of inflammatory cytokines in initiation and amplification of GVHD, clinical blockade of IL-1, IL-2, or TNF-α has not been

TABLE 110.7 Acute Graft-Versus-Host Disease Staging by Consensus Criteria[34]

Stage	Skin	Liver (Bilirubin)	Gastrointestinal
0	No skin rash	<2 mg/dL	<50 mL/day or persistent nausea alone
1	Maculopapular rash <25% BSA	2.1–3 mg/dL	500–1000 mL/day, or persistent nausea, vomiting, anorexia, or positive upper GI biopsy
2	Maculopapular rash 25%–50% BSA	3.1–6 mg/dL	1000–1500 mL/day
3	Maculopapular rash >50% BSA	6.1–15 mg/dL	>1500 mL/day
4	Generalized erythroderma, plus bullae or desquamation	>15 mg/dL	> 2000 mL/day, severe abdominal pain ±ileus

Clinical Grade	Skin	Liver	Gastrointestinal
I	Stage 1–2	None	None
II	Stage 3 or	Stage 1 or	Stage 1
III	—	Stage 2–3 or	Stages 2–4
IV	Stage 4 or	Stage 4	—

[a] Milliliter/day of liquid stool.
BSA, Body surface area; *GI*, gastrointestinal.

effective in GVHD prophylaxis. The most commonly used backbone of most GVHD prevention strategies includes calcineurin inhibitors with methotrexate or mycophenolate with or without antithymocyte globulin. In the last decade, high-dose post-transplant cyclophosphamide has emerged as a valuable GVHD prevention strategy in the context of haploidentical donor HCT. Several randomized trials are evaluating this strategy in transplant strategies using donors other than haploidentical related donors. In a phase III trial post-transplant cyclophosphamide was found to reduce the incidence of severe acute GVHD and chronic GVHD compared cyclosporine-based prophylaxis in matched related and unrelated donor RIC/NMA allo-HCT.[38]

Treatment of Acute Graft-Versus-Host Disease

Therapy for acute GVHD requires both immunosuppression to negate the T-cell mediated immune response that causes tissue injury and appropriate supportive care. Corticosteroids are the mainstay of initial therapy. GVHD involving limited areas of the skin (stage 1 to 2, overall grade I) can be treated with topical corticosteroids alone. Oral beclomethasone can be used to treat isolated GVHD of the upper gastrointestinal tract. Systemic corticosteroids (2 mg/kg/day prednisone or equivalent) are the standard initial therapy of more advanced GVHD with an expected response rate of ~50%. No regimen has shown a consistent increase in response rates or improvement in survival compared to corticosteroids alone. In a phase II randomized trial comparing corticosteroids with mycophenolate, pentostatin, etanercept or denileukin diftitox, efficacy and toxicity data suggested the combination of mycophenolate plus corticosteroids to be most promising in the initial therapy of acute GVHD.[39] However, this combination did not yield any improvements over corticosteroids alone in a randomized phase III trial.[40] For steroid refractory acute GVHD outcomes are generally poor. Salvage therapy with antithymocyte globulin or other agents like sirolimus, tacrolimus, MMF, pentostatin or cyclosporine yields a response rate of about 10% to 40%. The selective Janus kinase inhibitor ruxolitinib was compared to the investigator's choice second-line therapy for steroid-refractory acute GVHD in a large phase III trial and showed significant improvement in response rates at day +28 (62% vs. 39%).[41] Ruxolitinib is now FDA approved for this indication. Monoclonal antibodies and immunotoxins directed against T-cells or inflammatory cytokines have been investigated, although their effectiveness has not been demonstrated outside of small case series. Specific agents with reported activity in steroid-refractory acute GVHD include pentostatin, etanercept and infliximab (TNF-α receptor blockers), dacluzimab and denileukin diftitox (IL-2 receptor inhibitors), visilizumab (anti-CD3 antibody), and α-1 antitrypsin (protease inhibitor). Extra-corporeal photopheresis (ECP) has been reported to have some efficacy in steroid refractory acute GVHD. In addition to effective immunosuppression, successful management of acute GVHD involves attention to supportive care, particularly skin care, nutrition, and limitation of polypharmacy-associated drug interactions. Infections are a leading cause of death in patients with GVHD and attention should be paid to infection surveillance and prophylaxis.

TABLE 110.8 Common Clinical Manifestations of Chronic Graft-Versus-Host Disease[35]

Organ System	Clinical Manifestations
Cutaneous	Poikiloderma, lichen planus, dermal sclerosis, morphea-like features, hypo- or hyper-pigmentation, ichthyosis, nail dystrophy, onycholysis
Ocular	Keratoconjunctivitis sicca, conjunctivitis, corneal ulcerations
Oral	Lichen planus, hyperkeratotic plaques, xerostomia, mucosal atrophy, ulcers, restriction of mouth opening from sclerosis
Pulmonary	Bronchiolitis obliterans, bronchiolitis obliterans-organizing pneumonia (BOOP)
Gastrointestinal	Esophageal web and strictures, malabsorption syndrome, exocrine pancreatic insufficiency
Hepatic	Cholestasis
Genitourinary	Vaginal stenosis or scarring, lichen planus
Musculoskeletal	Fasciitis, joint contractures from sclerosis, myositis or polymyositis, arthritis
Hematopoietic	Thrombocytopenia, eosinophilia, lymphopenia, hemolytic anemia, hypogammaglobulinemia

Chronic Graft-Versus-Host Disease

Risk Factors and Clinical Features

Chronic GVHD is a complex syndrome that affects allogeneic HCT patients to varying degrees. Usually presenting beyond day +100, the diagnosis is based on clinical presentation rather than timing alone. Preceding acute GVHD, unrelated donor HCT and peripheral blood as the graft source are the main risk factors for subsequent chronic GVHD. Like acute GVHD, ex vivo or in vivo T-cell depletion of the graft can reduce the incidence of chronic GVHD.

Chronic GVHD can affect any organ system; however, certain pathognomonic clinical signs and symptoms aid in establishing the diagnosis (Table 110.8).[35] Histological confirmation, though not always required, may help confirm the diagnosis and rule out other etiologies, especially when patients exhibit unusual presentation. The skin, mouth, eyes, and liver are the most commonly involved sites of chronic GHVD. The cutaneous manifestations resemble autoimmune disease and can include poikiloderma, lichen planus-like eruptions or scleroderma. An inflammatory dermatitis can progress to severe dermal and periarticular fibrosis with loss of skin appendages (hair and sweat glands) as well as significant skin tightness, fasciitis, and loss of joint flexibility. Additional manifestations include dry eyes and mouth, which can resemble Sjögren's syndrome clinically and histologically; enteritis with anorexia, early satiety, malabsorption, weight loss and failure to thrive, or esophageal dysmotility or stricture; and cholestatic (rarely hepatitic) jaundice. Pulmonary involvement in the form of bronchiolitis obliterans is an uncommon manifestation but can be particularly debilitating and lethal. In addition, the profound immune dysfunction associated with chronic GVHD, due to hypogammaglobulinemia, impaired cellular immunity and functional asplenia, greatly increases the risk of secondary infections from bacteria, viruses, and fungi. After the onset of chronic GVHD, 25% to 40% of patients die within 2 years, with infections often being the immediate cause. Chronic GVHD can be classified as mild, moderate, or severe depending on the number of organs involved and the degree of individual organ involvement. In general, factors associated with an adverse prognosis include thrombocytopenia, progressive onset from acute GVHD, poor performance status, lack of response to initial therapy and extensive skin or lung involvement.

Treatment of Chronic Graft-Versus-Host Disease

Although acute GVHD is one of the strongest predictors for chronic GVHD, strategies to limit acute GVHD, such as prolonging or intensifying initial immunosuppression, have not been consistently effective in preventing subsequent chronic GVHD. As with acute GVHD, the use of corticosteroids, usually in combination with calcineurin inhibitor, is the mainstay of therapy. The protracted nature of chronic GVHD syndrome warrants long-term therapy. Lowest possible doses and alternate day steroid therapy are useful strategies to potentially minimize the chronic complications of prolonged corticosteroid therapy. Typical corticosteroid regimens start with daily prednisone 1 mg/kg/day and responding patients are tapered as tolerated. Chronic immunosuppression is usually continued long-term even for quiescent chronic GVHD to avoid exacerbations. Local treatment strategies targeting affected organ systems (e.g., cyclosporine eye drops, dexamethasone mouth rinses) are useful in limiting systemic immunosuppression, especially for limited stage chronic GVHD. For chronic GVHD that is steroid-dependent or refractory, salvage therapies are needed. If not already on it, a calcineurin inhibitor may be added. Other therapeutic options include sirolimus, mycophenolate, ruxolitinib, ibrutinib (FDA approved), rituximab, and imatinib. Most salvage strategies work by modulation of T-cell function, B-cell depletion, induction of immune tolerance, and cytokine blockade. T-cell immunomodulation using extracorporeal photopheresis has been shown to have some activity, especially in sclerotic cutaneous chronic GVHD. The treatment of chronic GVHD demands attention to aggressive antimicrobial prophylaxis and immunizations to prevent opportunistic infections. Most successful strategies for treating chronic GVHD incorporate long-term reduced-dose immunosuppressive therapy, aggressive antimicrobial prophylaxis, and supportive care. Strategies favoring development of donor-derived regulatory T cells (Tregs) which may facilitate the development of immunologic tolerance are being studied.

FUTURE DIRECTIONS

Complications of HCT are one of the major barriers to the wider application of transplantation for a variety of diseases. Currently, only one in four adult HCT recipients survives to 1 year post-HCT without experiencing a major complication. The impact of newer transplantation modalities, including the use of NMA/RIC regimens, alternative donor transplantation with haploidentical donor and UCB, and incorporation of immune-based therapies within transplantation regimens, on early and late complications continue to evolve. Better tools to predict the risk of post-HCT complications and NRM are needed as well. Genomic and proteomic approaches to HCT complications are being investigated to monitor and predict complications. Although they are some years from use in clinical practice, these approaches could have many potential applications in transplantation, including prediction of risk for complications and GVHD, refining donor selection, and utilization of pharmacogenomic data to individualize conditioning regimens and immunosuppression. Each of these facets represent areas of ongoing vigorous research to improve the safety and effectiveness of HCT.

PART X TRANSFUSION MEDICINE

CHAPTER 111

HUMAN BLOOD GROUP ANTIGENS AND ANTIBODIES

William J. Lane, Connie M. Westhoff, Jill R. Storry, and Beth H. Shaz

Pretransfusion testing includes ABO and Rhesus (Rh) type, and antibody screening to determine whether a patient has an unexpected red blood cell (RBC) antibody. If the antibody screen is positive, an identification panel is performed to identify the specificity. Unexpected antibodies can be clinically significant causing hemolysis (i.e., acute or delayed hemolytic reaction) after transfusion of RBCs carrying the reciprocal antigen, or can be insignificant. The clinical significance of an antibody is assessed by correlating the serologic information with clinical experiences reported in the literature and with the patient's medical history. Notably, the majority of clinically significant antibodies (outside the ABO system) are in response to RBC antigen exposure either through transfusion or pregnancy. Other antibody characteristics that are used to predict clinical significance include immunoglobulin (Ig) class and in vitro characteristics such as strength of reactivity and titer; however, no foolproof method exists to predict the clinical significance. For antibodies with well-known clinical significance, antigen-negative blood is selected for transfusion. Predicting clinical significance is more difficult when a patient has an antibody to a novel or rare high-prevalence antigen, and requires a transfusion but antigen-negative blood is not available.

ERYTHROCYTE BLOOD GROUP ANTIGENS

Erythrocyte blood group antigens are polymorphic, inherited, carbohydrate, or protein structures located on the surface of the RBC membrane. There are more than 300 blood group antigens, most of which are included in 38 different blood group systems (Table 111.1). The protein antigens are primarily located on integral transmembrane proteins, but a few are on glycosylphosphatidylinositol (GPI)–linked proteins (Fig. 111.1). Some antigens are carbohydrates attached to proteins or lipids, some require a combination of a specific portion of protein and carbohydrate, and a few antigens are carried on proteins that are adsorbed from the plasma. Many of the proteins carrying blood group antigens reside in the erythrocyte membrane as complexes with other proteins.

Recognition of a new blood group antigen begins with discovery of an antibody. When an individual whose RBCs lack an antigen is exposed to RBCs that possess the antigen, they may mount an immune response and produce antibodies that react with the antigen. Depending on the characteristics of the antibody and the number and topology of antigens in the RBC membrane, the interaction in vivo between antibody and antigen may result in removal of antibody-coated RBCs by the reticuloendothelial system or in hemolysis if complement is activated.

In blood group testing, most assays are designed to detect antibody-antigen binding with clumping of the RBCs ("agglutination") as the detectable endpoint. The ability to detect and identify blood group antigens and antibodies has contributed significantly to current safe supportive blood transfusion practice, to the appropriate management of pregnancies at risk for hemolytic disease of the fetus and newborn (HDFN), and to management of hematopoietic progenitor cell and solid organ transplantation.

Terminology

Some blood group systems bear the family surname in which the antibody was first discovered (Kell, Kidd, Duffy, etc.), with abbreviations to indicate antigens (K/k, Jk^a/Jk^b, Fy^a/Fy^b, etc.). Others have been given letter designations (A, B, D, M, N, etc.). A committee for terminology of RBC surface antigens and alleles, organized by the International Society of Blood Transfusion (ISBT), works to standardize terminology of new blood group antigens and the coding alleles.

DNA-Based Typing for Blood Group Antigens

The majority of genes encoding blood group antigens have been identified and cloned, and the molecular basis of most blood group antigens has been determined.[1,2] Details concerning the alleles associated with blood group antigens are found on the ISBT Red Cell Immunogenetics and Blood Group Terminology working party webpage, and the Blood Antigens and Erythrogene websites (www.isbtweb.org/working-parties/red-cell-immunogenetics-and-blood-group-terminology/; bloodantigens.com; erythrogene.com). Knowledge of the genes has advanced understanding of the structure and function of the components carrying antigens, and resulted in an appreciation of diseases associated with loss of expression of some blood groups, for example, null phenotypes (see Table 111.1). Of importance, knowledge of the gene has made it possible to perform DNA analyses to predict the serologic phenotype, to determine gene dosage (zygosity), to perform noninvasive fetal typing, and to type for numerous blood group antigens in a single assay.

Although the simple hemagglutination test remains the principal assay for RBC antigen typing for ABO and Rh, antibody screen, and compatibility testing; DNA-based typing (genotyping), especially for the minor blood group antigens, has become commonplace in some clinical situations (Table 111.2).[3] These include determination of the extended blood group phenotype in patients who are multiply transfused, which avoids false typing because of contaminating donor RBCs and aids determination of antibody specificity. This approach is also preferred in patients with strongly direct antiglobulin test (DAT)-positive RBCs, as well as for typing for antigens when no serologic reagents are available and for fetal typing from amniocytes or from free DNA present in the maternal plasma. In these instances[4] and others (see Table 111.2), hemagglutination is not helpful, and genomic analysis is a useful adjunct to routine testing. More recently, genotyping is useful in patients treated with daratumumab (anti-CD38) because treatment results in panreactivity on antibody

TABLE 111.1 Blood Group Systems, Antigens, Expression, and Disease Associations

ISBT System Name (Number)	Gene Name	Predicted Topology (Number of Amino Acids [AA])	Component Name	Principal Associated Blood Group Antigens (Null Phenotype)	Present in Other Tissue	Disease Association	Function
ABO (001)	*ABO*	Glycosyl-transferases Type II^a (354 AA)	Carbohydrate	A, B, AB, A1 (group O)	Secretions, platelets, broad tissue distribution	Altered in some hematologic disorders, leukemia	Glycosylation
MNS (002)	*GYPA (MN)* *GYPB (Ss)*	Type I (131 AA) Type I^a (72 AA)	GPA GPB	M, N, S, s, U, Vw; M^k M^k lack GPA and GPB; En(a–) lack GPA; S–s–U– lack GPB	Renal endothelium and epithelium	Decreased *Plasmodium falciparum* invasion May be receptor for *Escherichia coli*	Negative charge on sialic acid; receptor for microbes
P1PK (003)	*A4GALT*	Galactosyl-transferase Type II (353 AA)	Carbohydrate	P1, Pk (P1–, PP1Pk–)	Lymphocytes, granulocytes, monocytes, platelets	Receptor *E. coli* and *Parvovirus-B19* Miscarriage	Glycosylation
Rh (004)	*RHD* *RHCE*	Multipass—12 spans (417 AA)	RhD RhCE	D, C, E, c, e, G, V/VS (Rh$_{null}$ syndrome)	RBC-specific	Hemolytic anemia; stomatocytosis Reduced expression and mosaicism in hematologic malignancies	Structural link to underlying cytoskeleton
Lutheran (005)	*BCAM* *(LU)*	Type I IgSF (597 AA) (557 AA)	Lutheran glycoprotein B-CAM	Lu^a, Lu^b, Lu3, Au^a, Au^b (recessive Lu(a–b–))	Broad tissue distribution Not on lymphocytes, granulocytes, monocytes or platelets	Increased expression possibly involved in vasoocclusion in sickle cell disease	Possibly adhesion; may mediate intracellular signalling Binds to laminin
Kell (006)	*KEL*	Type II (732 AA)	Kell glycoprotein	K, k, Kp^a, Kp^b, Ku, Js^a, Js^b (K$_0$ or K$_{null}$)	Broad tissue distribution Bone marrow, fetal liver, testes, brain, heart, skeletal muscle	Depressed in McLeod syndrome (see XK)	Cleaves big endothelin 3 to ET-3 (a potent vasoconstrictor)
Lewis (007)	*FUT3 (LE)*	Not endogenous to RBCs Type II (361 AA)	Carbohydrate Adsorbed from plasma	Le^a, Le^b, Le^{ab}, Le^{bh}, ALe^b, BLe^b (Le(a–b–))	Saliva and body fluids, Blood cells, GI, skeletal muscle, kidney, adrenal	Increased expression in fucosidosis	Fucosyl transferase
Duffy (008)	*ACKR1 (DARC, FY)*	Multipass—7 spans (338 AA)	Fy glycoprotein	Fy^a, Fy^b, Fy3, Fy6 (Fy(a–b–))	Broad tissue distribution Endothelial and epithelial cells, Purkinje cells, colon, lung, spleen, thyroid, thymus, kidney	*Plasmodium vivax* receptor RBC null-resistant to *P. vivax*	Chemokine receptor
Kidd (009)	*SLC14A1 (JK)*	Multipass—10 spans (389 AA)	Kidd glycoprotein	Jk^a, Jk^b, Jk3 (Jk(a–b–) or Jk$_{null}$)	Kidney: vasa recta endothelium Renal medulla	Urine concentrating defect	Urea transport
Diego (010)	*SLC4A1 (DI)*	Multipass—14 spans (911 AA)	Band 3, AE1	Di^a, Di^b, Wr^a, Wr^b, (1 reported—transfusion dependent; predicted to be incompatible with life)	Kidney: intercalated cells of distal and collecting tubules	Southeast Asian ovalocytosis, hereditary spherocytosis, renal tubular acidosis	Anion transport CO_2/HCO_3^- exchange

TABLE 111.1 Blood Group Systems, Antigens, Expression, and Disease Associations—cont'd

ISBT System Name (Number)	Gene Name	Predicted Topology (Number of Amino Acids [AA])	Component Name	Principal Associated Blood Group Antigens (Null Phenotype)	Present in Other Tissue	Disease Association	Function
Yt (011)	*ACHE (YT)*	GPI-linked (557 AA)	Acetyl-cholinesterase	Yt^a, Yt^b	Brain, muscle, nerves	Absent from PNH III RBCs	Enzymatic
Xg (012)	*XG*	Type I (180 AA) (163 AA)	Xg^a glycoprotein	Xg^a	The antigen may be restricted to RBC, but CD99 has broad tissue distribution		Adhesion molecule
Scianna (013)	*ERMAP (SC)*	Type I (475 AA)	ERMAP	Sc1, Sc2, Sc3, Rd (Sc −1, −2, −3)			Possible adhesion
Dombrock (014)	*ART4 (DO)*	GPI-linked (314 AA)	Do glycoprotein; ART 4	Do^a, Do^b, Gy^a, Hy, Jo^a (Gy(a−))	Lymphocytes, spleen, lymph nodes, GI, ovary, testes, heart, liver	Absent from PNH III RBCs	Enzymatic
Colton (015)	*AQP1 (CO)*	Multipass—6 spans (269 AA)	Aquaporin	Co^a, Co^b, Co3 (Co(a−b−))	Broad tissue distribution Kidney, liver, gallbladder, eye, capillary endothelium	Monosomy 7, congenital dyserythropoietic anemia	Water transport
Landsteiner-Wiener (016)	*ICAM4 (LW)*	Type I IgSF (241 AA)	LW glycoproteinICAM-4	LW^a, LW^b, LW^{ab}(LW(a−b−))		Depressed in some malignant diseases; decreased in Rh$_{null}$ syndrome	Ligand for integrins
Chido/ Rodgers (017)	*C4A, C4B (CH/RG)*	Not endogenous to RBC (1191 AA)	C4A; C4B	Ch1, Ch2, Rg1	Adsorbed from plasma	Certain phenotypes increased susceptibility to autoimmune conditions and infections C4-deficient Predisposes for SLE	Part of the complement cascade
H (018)	*FUT1(H)*	Fucosyl-transferase Type II (365 AA)	Carbohydrate	H (Bombay O$_h$)	Broad distribution Soluble—all fluids except CSF in secretors	Decreased in some tumor cells Increased in hematopoietic stress	Glycosylation
Kx (019)	*XK (XK)*	Multipass—10 spans (444 AA)	XK glycoprotein	Kx (McLeod)	Fetal liver, adult skeletal muscle, brain, pancreas, heart	X-linked midlife onset neuropathy, elevated CPK, muscular dystrophy, acanthocytosis; sometimes associated with CGD	Transport; possible neurotransmitter
Gerbich (020)	*GYPC (GE)*	Type I (128 AA) (107 AA)	GPC GPD	Ge2, Ge3, Ge4 (Leach phenotype)	Fetal liver, renal endothelium	Hereditary elliptocytosis, hemolytic anemia, receptor *P. falciparum*	Structural Interacts with protein 4.1 and p55

ISBT System Name (Number)	Gene Name	Predicted Topology (Number of Amino Acids [AA])	Component Name	Principal Associated Blood Group Antigens (Null Phenotype)	Present in Other Tissue	Disease Association	Function
Cromer (021)	*CD55 (CROM)*	GPI-linked (347 AA)	DAF	Cr^a, Tc^a, Tc^b, Tc^c, Dr^a, Es^a, IFC (Inab)	Vascular endothelium Epithelial GI, GU, CNS Soluble form in plasma and urine	Absent from PNH III RBCs Dr^a is receptor for uropathogenic *E. coli*	Complement regulation; binds C3b; disassembles C3/C5 convertase
Knops (022)	*CR1 (KN)*	Type I (1998 AA)	CR1	Kn^a, Kn^b, McC^a, Sl^a, Yk^a, KCAM (no nulls reported)	Blood cells, glomerular podocytes, follicular dendritic cells	Antigens depressed in certain autoimmune and malignant conditions	Complement regulation; binds C3b and C4b; mediates phagocytosis
Indian (023)	*CD44 (IN)*	Type I (341 AA)	Hermes antigen	In^a, In^b	Wide tissue distribution	1 case—congenital dyserythropoietic anemia	Binds hyaluronic acid; mediates adhesion of leukocytes
Ok (024)	*BSG (OK)*	Type I IgSF (248 AA)	Basigin	Ok^a	All cells tested	Receptor *P. falciparum*	Possible adhesion
RAPH (025)	*MER2*	Multipass—4 spans (253 AA)	CD151	MER2 (Raph–)	Fibroblasts	Absence associated with renal disease and kidney failure	
JMH (026)	*SEMA7A(JMH)*	GPI-linked (656 AA)	Semaphorin 7A	JMH		Absent from PNHIII RBCs	Adhesion molecule
I (027)	*GCNT2*	*N*-acetyl-glucosaminyl-transferase type II (400 AA)	Carbohydrate	I (I– or i adult)	Broad tissue distribution	Cataracts in Asians	Glycosylation
Globoside (028)	*B3GALT1*	*N*-acetyl-galactosaminyl-transferase type II (331 AA)	Carbohydrate (Gb$_4$, globoside)	P (P–) P^k and p	Broad tissue distribution Placenta (trophoblasts and interstitial cells)	Receptor *E. coli* and *Parvovirus-B19* Spontaneous abortion	Glycosylation
GIL (029)	*AQP3 (GIL)*	Multipass—6 spans (292 AA)	AQP3	GIL (GIL–)	Board tissue distribution Kidney, prostate, GI tract, spleen, skin, eye		Glycerol/ water/ urea transport
RHAG (030)	*RHAG*	Multipass—12 spans (409 AA)	Rh-associated glycoprotein	RHAG1 or Duclos, RHAG2 or Ol^a, RHAG3 or DL, RHAG4 (Rh$_{null}$ regulator)	RBC-specific but homologs RhBG, RhCG in kidney, liver, skin, GI tract	Hereditary overhydrated stomatocytosis	Ammonia transport
FORS (031)	*GBGT1*	Type II (347 AA)	Carbohydrate	FORS1	Broad tissue distribution		Glycosyltransferase
JR (032)	*ABCG2*	Type III—6 spans (655 AA)	ATP-binding cassette sub-family G member 2	Jr^a (Jr(a–))	Broad tissue distribution High in placenta, seminal vesicles	Gout; multidrug resistance in cancer	Urate exporter; porphyrin hemostasis
LAN (033)	*ABCB6*	Type III—6 spans (842 AA)	ATP-binding cassette sub-family B member 6, mitochondrial	Lan (Lan–)	Broad tissue distribution	Dyschromatosis universalis hereditaria; Microphthalmia	Binds heme and porphyrins. Important in heme synthesis

TABLE 111.1 Blood Group Systems, Antigens, Expression, and Disease Associations—cont'd

ISBT System Name (Number)	Gene Name	Predicted Topology (Number of Amino Acids [AA])	Component Name	Principal Associated Blood Group Antigens (Null Phenotype)	Present in Other Tissue	Disease Association	Function
VEL (034)	*SMIM1*	Type 1 (78 AA)	SMIM1	Vel (Vel–)	RBCs, salivary glands, testis		Not known
CD59 (035)	*CD59*	GPI-linked (128 AA)	CD59 glycoprotein	CD59.1 (CD59.1–)	Broad tissue distribution; soluble form in plasma	Hemolytic anemia, with or without polyneuropathy	Complement regulation; inhibits MAC complex
AUG (036)	*SLC29A1*	Type III—11 spans (456 AA)	Equilibrative nucleoside transporter 1	At^a (At(a–)	Broad tissue distribution	Pseudo gout in the null phenotype	Nucleoside transmembrane transporter
KANNO (037)	*PRNP*	(253 AA)	Prion	KANNO	Broad tissue distribution	Absence of KANNO possibly protective for Creutzfeldt-Jakob disease	Possible role in neuronal development and synaptic plasticity
Sid (038)	*B4GALNT2*	Beta-1,4 N-acetylgalactosaminyltransferase 2 (566 AA)	Carbohydrate	Sd^a ((Sd(a–))	Kidney, colon, stomach	Extra strong expression of Sd^a Sd(a++) makes cells resistant to malarial parasite *P. falciparum*	Glycosylation

Type I, protein with a single pass through the RBC lipid bilayer with its amino terminus to the outside of the cell; type II, protein with a single pass through the RBC lipid bilayer with its amino terminus to the inside of the cell. *AE1*, Anion exchanger 1; *AQP*, aquaporin; *C4*, fourth component of complement; *CGD*, chronic granulomatous disease; *CR1*, complement receptor 1; *CSF*, colony-stimulating factor; *CNS*, central nervous system; *DAF*, decay-accelerating factor; *ERMAP*, erythrocyte membrane-associated protein; *GPA*, glycophorin A; *GPB*, glycophorin B; *GPC*, glycophorin C; *GPD*, glycophorin D; *GI*, gastrointestinal; *GPI*, glycosylphosphatidylinositol; *GU*, genitourinary; *ICAM4*, intercellular adhesion molecule 4; *IgSF*, immunoglobulin super family; *ISBT*, International Society of Blood Transfusion; *PNH*, paroxysmal nocturnal hemoglobinuria; *RBC*, red blood cell; *SLE*, systemic lupus erythematosus.

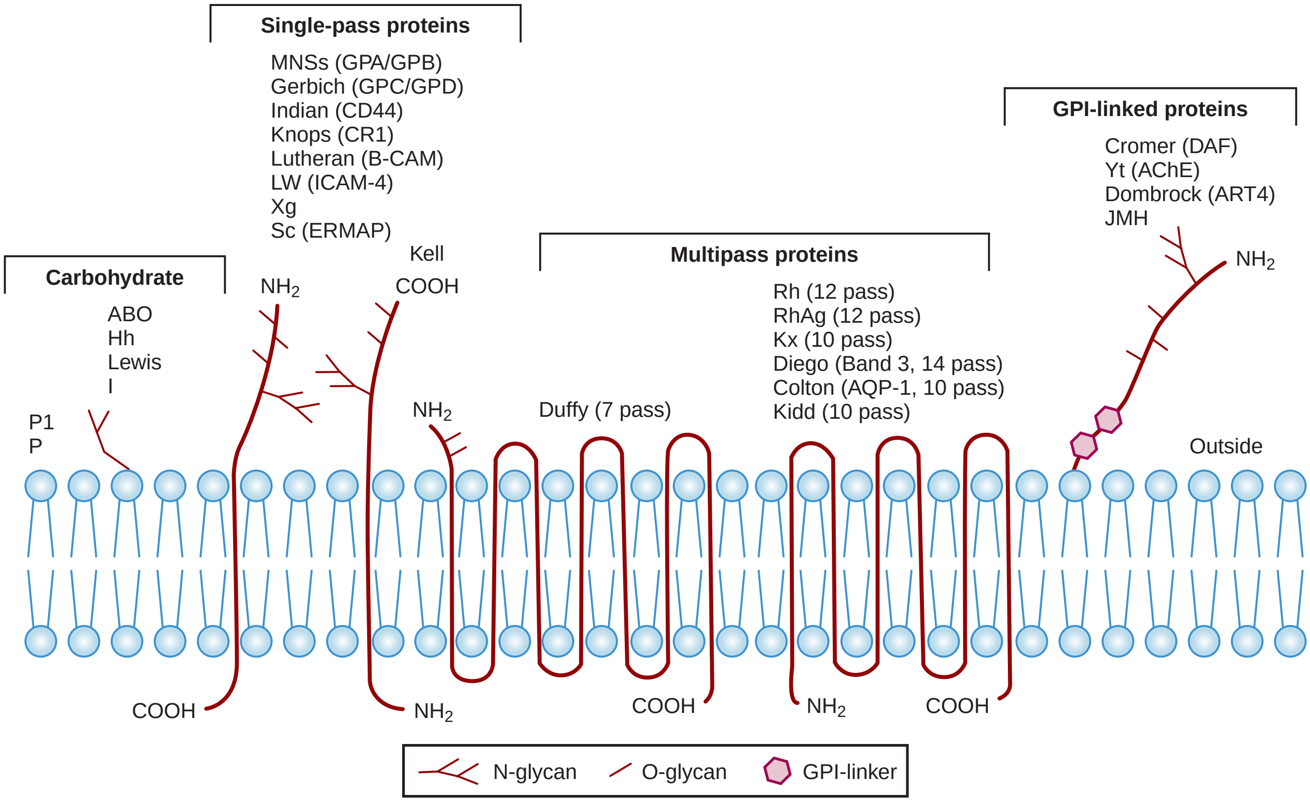

Figure 111.1 MODEL OF BLOOD GROUP PROTEINS IN THE RED BLOOD CELL MEMBRANE. Schematic representation of the red blood cell (RBC) molecules that carry blood group antigens and the predicted type of structure. These include carbohydrates, single and multipass proteins, and GPI-linked proteins in the RBC membrane (represented by the blue molecules arranged as a bilayer). Note that not all blood group–bearing structures are listed but those that are more commonly encountered. NH_2 indicates orientation of the N-terminus of the protein; COOH indicates the orientation of the C-terminus. Glycosylation of proteins is shown as indicated, and may be small O-linked carbohydrate chains or more complex N-linked sugar structures. The extracellular surface of the lipid bilayer is also heavily glycosylated with blood group–bearing carbohydrates.

TABLE 111.2 **Uses of DNA-Based Genotyping Assays for Transfusion Medicine**

Type patients who have been recently transfused
Type patients who are being treated with monoclonal antibody therapy, for example anti-CD38
Type RBCs coated with immunoglobulin
Type patients with AIHA (to select antigen-negative RBCs for transfusion and absorption of autoantibodies when searching for underlying alloantibodies)
Type RBCs when commercial antisera are not available
Type for numerous blood group antigens in a single assay
Identify weak D and partial D (to determine candidate for Rh immune globulin or avoid use of limited Rh-negative donor supply)
Resolve blood group typing discrepancies
Determine paternal zygosity for *RHD* and HPA
Type fetus to determine risk for HDFN or NAIT
ABO genotyping of buccal swabs for screening of stem cell transplant donors

AIHA, Autoimmune hemolytic anemia; *HDFN*, hemolytic disease of the fetus and newborn; *HPA*, human platelet antigen; *NAIT*, neonatal alloimmune thrombocytopenia; *RBC*, red blood cell.

screening (all cells being reactive). High-throughput genotyping systems have enabled blood centers to screen donors for a large number of antigens in a single assay. *RHD* genotyping is also well suited for the precise determination of known weak D and partial D variations.

Polymerase chain reaction (PCR) -based genotyping assays currently dominate the market. However, next generation sequencing (NGS) has proven to be a naive, but promising approach.[5,6] NGS allows for the sequencing of large genomic regions, making it ideal for novel antigen discovery, and has been used to determine the genetic basis of several recent blood group systems. Interpretation of NGS based whole genome and whole exome data can be used to genotype for essentially all antigens with a known genetic basis. Furthermore, the development of automated interpretive software has allowed for genotyping from large scale genomic sequencing projects. In addition, targeted NGS of either one or multiple blood group genes is possible, including the ABO and Rh blood group systems. Targeted NGS based *ABO* genotyping particularly has value alongside NGS based human leukocyte antigen (HLA) typing of buccal swabs when screening stem cell transplant donors. In addition, NGS, especially whole genome sequencing (WGS), is well suited for the evaluation of structural variations including large deletions (e.g. MNS U– *GYPB* deletion) and gene recombinations (e.g., Rh partial D DIIIa-CE(4-7)-D).

Blood Group Antibodies

The common causes of immunization against blood group antigens are transfusion, pregnancy, transplantation, or occasionally, practices such as sharing needles. “Naturally occurring” antibodies are not a result of RBC exposure; rather, a response to microbes encountered by way of the digestive tract and other mucosal surfaces regularly (e.g., anti-A, anti-B,) or sometimes (e.g., anti-M, -P, -P^k, -P1, -Le^a, -Le^b, -I, -IH) which result in production of antibodies with these specificities. These are the most common antibodies present in children and nontransfused male patients, and are primarily

TABLE 111.3 **Characteristics of Some Blood Group Alloantibodies (Listed in Approximate Order of Clinical Significance)**

Antibody Specificity	IgM	IgG	Clinical	
			Transfusion Reaction	**HDFN**
ABO	Most	Some	Immediate; mild to severe	Common; mild to moderate
H in Bombay	Most	Some	Immediate; mild to severe	Rare; mild

[a] Most examples of these antibodies are both IgM and IgG.

[b] Seldom hemolysis of fetal cells but high incidence of recurrent spontaneous abortions.

IgG, Immunoglobulin G; *IgM*, immunoglobulin M; *HDFN*, Hemolytic disease of the fetus and newborn; *Rh*, rhesus; *RhAG*, Rh-associated glycoprotein.

IgM. These multivalent IgM antibodies directed to carbohydrate antigens optimally bind and directly agglutinate to RBCs at temperatures below 37°C. Most are not clinically significant (outside of ABO). Exceptions occur if the antibody is reactive at 37°C and/or has an IgG component. Antibodies that are considered not to be clinically significant unless the antibody reacts in tests performed at 37°C include those to A1, P1, M, N, Lu^a, Le^a, Le^b, I, IH, and Sd^a antigens.

In contrast, antibodies occurring following immunization to protein antigens such as those in the Rh, Kell, Kidd, and Duffy blood group systems are primarily of the IgG isotype that react at 37°C and are detected by the indirect antiglobulin test (IAT). These bivalent antibodies optimally bind to, but do not directly agglutinate, RBCs at 37°C. The addition of an antiglobulin reagent (i.e., antihuman globulin [AHG], also known as Coombs serum) is required to induce RBC agglutination. Most of these are clinically significant antibodies, with the exception of antibodies to Knops (Kn), Chido/Rodgers (Ch/Rg) and John Milton Hagen (JMH) systems (Table 111.3 summarizes the Ig class and clinical significance associated with alloantibodies; see also box on Indirect Antiglobulin Test and Direct Antiglobulin Test).

Antibodies recognizing antigens in the ABO system are by far the most clinically significant and are present in nearly all individuals who lack the antigen (they typically appear by 4 months of age). Other clinically significant antibodies occur in the following approximate order, from the most to the least commonly encountered in transfusion practice: anti-D, anti-K, anti-E, anti-c, anti-Fy^a, anti-C, anti-Jk^a, anti-S, and anti-Jk^b. Clinically significant antibodies occur in approximately 3% of transfused patients[7] but have a higher incidence of 35% to 55% in patients undergoing chronic transfusion.[8–12] The frequency of antibody production depends on the antigen immunogenicity and prevalence of the antigen in a population.

Compatibility Procedures and Location of Antigen-Negative Blood

Manual tube, solid phase, or gel-column methods based on agglutination of RBCs are the most common serologic assays performed in transfusion medicine laboratories.

INDIRECT ANTIGLOBULIN TEST AND DIRECT ANTIGLOBULIN TEST

The indirect antiglobulin test (IAT) is used to detect alloantibodies in patient sera in vitro following incubation at 37°C and includes antibody screening and identification and crossmatching with donor red blood cells (RBCs). IAT is also sometimes used for antigen typing to detect RBCs coated with antibody following incubation with reagent antisera. After incubation, unbound antibodies are removed by washing with saline and an antiglobulin reagent containing either antihuman IgG (AHG) or a mixture of AHG and monoclonal antihuman complement is added. Differential agglutination suggests the presence of antibodies to one or more specific RBC antigens while agglutination of all cells suggests the presence of an antibody to a high-prevalence antigen or the presence of an autoantibody.

The direct antiglobulin test (DAT) is used to detect the presence of antibody or complement (or both) on the surface of RBCs in vivo such as autoantibodies coating the patient's cells in warm autoimmune hemolytic anemia, cold hemagglutinin disease, or alloantibodies coating the patient's cells in immediate or delayed transfusion reactions, or hemolytic disease of the fetus and newborn. Patient RBCs obtained in ethylenediaminetetraacetic acid, to prevent in vitro complement deposition on the RBCs, are washed with saline and then incubated with a commercial antiglobulin reagent containing AHG or antihuman complement or a mixture of the two. Antiglobulin reagents containing anti-IgM or anti-IgA are available in specialized centers to detect coating of RBCs by antibodies of these isotypes.

Rh IMMUNE GLOBULIN

Rh immune globulin (RhIG) is a human plasma-derived hyperimmunoglobulin product consisting of IgG antibodies to D antigen that is administered to D-negative pregnant women who are at risk for D sensitization. RhIG is administered (1) at 28 weeks gestational age, (2) when there is a risk for fetal maternal hemorrhage through amniocentesis, trauma, or other procedures, and (3) postpartum in the case of a known or potential D-positive newborn or fetus. If the Rh(D) typing of a pregnant woman is discrepant with prior results, or typing reactions are weaker than expected, or if variable reactivity is seen, RHD genotyping should be considered to guide RhIG prophylaxis and selection of blood for transfusion.

RhIG is sometimes administered outside of pregnancy to D-negative patients who receive D-positive blood products, most commonly whole blood derived platelet products. This is primarily considered for females of childbearing potential when the formation of anti-D has serious consequences. Because the risk for D alloimmunization from whole blood derived platelet transfusion is less than 4%, and even less for apheresis platelets, the majority of D-incompatible platelets are given without RhIG administration. RhIG in significantly higher doses is used to treat immune thrombocytopenic purpura (ITP) in patients who are D-positive and have not been splenectomized.

For prevention of D-sensitization in the United States, 300 μg are routinely administered, but dosing is increased if there is evidence of large fetal-maternal hemorrhage (300 μg for every 15 mL of RBC exposure or 30 mL of whole blood exposure). The dose is calculated based on the estimated volume of D-positive fetal RBCs from Kleihauer-Betke or flow cytometry, which is more precise. RhIG dosing calculators are available. RhIG should be given within 72 hours, which was the time period for the original studies, but should not be withheld if not administered within this time period. Adverse events to low doses used to prevent D immunization include fever, chills, and pain at the injection site. Rarely, hypersensitivity reactions are noted. RhIG doses used to treat ITP are substantial: 50 μg/kg for hemoglobin values ≥10 g/dL and 25–40 μg/kg when hemoglobin is 8–10 g/dL. Adverse events include possible anemia, hemolysis, disseminated intravascular coagulopathy, and rarely, death (Chapter 131).

ABO

Commercially available mouse monoclonal anti-A and anti-B are used to determine ABO type, and these reagents directly agglutinate RBCs at room temperature. To confirm the RBC ABO reactivity, the plasma is tested for the presence of the corresponding agglutinins by testing with commercially available group A1 and group B RBCs. In both tests, agglutination is macroscopically visible.

Rhesus

Patient and donor RBCs are routinely tested for the presence of the D antigen in the Rh system. Reagents containing monoclonal anti-D that directly agglutinate D-positive (Rh-positive) RBCs suspended in saline at room temperature are commonly used for testing. Testing by a method that detects expression of a weak D antigen on RBCs is required for donors, but additional testing for weak D is optional when testing patient samples. Exceptions include typing the RBCs of a newborn when the mother is D-negative to determine whether she is a candidate for Rh immune globulin (RhIG) (see box on Rh Immune Globulin).

Antibody Screening

Patient plasma is incubated at 37°C with commercially available reagent RBCs of known antigen type. After incubation, unbound antibodies are removed by washing with saline, and an antiglobulin reagent containing either AHG, or a mixture of AHG and antihuman complement is added. Column agglutination technology is now widely used and eliminates the requirement to wash unbound IgG. If the antibody screen is positive, the specificity of the antibody is determined by testing the plasma against a panel of different group O reagent RBCs (usually 10) varying in antigen phenotype (termed antibody identification).

Compatibility Testing

Once a patient is actively immunized to an RBC antigen and produces a clinically significant alloantibody, the patient is considered immunized for life and should be transfused with antigen-negative RBCs, even if the antibody is no longer detectable. Patients with passively acquired antibody (e.g., neonates with maternal antibody; recipients of plasma and platelet products or RhIG) need to be transfused with antigen-negative RBCs only while the passive antibody is present. Selection of blood for transfusion to patients with alloantibodies requires typing of donor units for the corresponding antigen to identify antigen-negative units and crossmatch of the selected units with the patient's plasma. Antigen-negative units are provided by, or can be located by, most donor centers. Provision of antigen-negative blood will to some extent depend on the prevalence of the target antigen(s) in the donor population. Transfusion service staff are vital for communication between the patient's physician and/or consultant transfusion medicine specialist to determine the immediate and ongoing transfusion needs of the patient and to ensure that antigen-negative blood is available. Understanding the risks and benefits of transfusion are important, as well as understanding the potential clinical significance of the antibody and the urgency of transfusion. When a patient's antibody is directed at a high-prevalence antigen, it is important to test siblings in the quest for compatible blood and to urge the patient to donate blood for long-term storage when clinical status permits. In hemolytic anemia because of warm-reactive autoantibodies, compatibility may be difficult to demonstrate. In this scenario, the important issue is to be sure that there are no clinically significant alloantibodies underlying the warm reactive autoantibodies. Donor RBCs antigen-matched with the patient for clinically significant blood group antigens should be considered in lieu of transfusion with "least incompatible" blood to minimize alloimmunization.

Prevention of Alloimmunization

Transfusion management of patients who require chronic transfusion therapy, in particular patients with sickle cell disease can be challenging.[13–15] Many programs attempt to reduce or prevent alloimmunization by transfusion of RBCs that are prophylactically antigen-matched, typically for C, E, and K,[16] and some match for additional antigens. Some centers match for extended antigens once the patient makes an antibody (Table 111.4). The goal is to prevent

TABLE 111.4 Approaches to Supplying Red Blood Cell Products to Prevent Alloimmunization in Patients With Sickle Cell Disease or Other Transfusion-Dependent Anemia

Phenotype or genotype for clinically significant antigens before transfusion
Provide antigen-matched blood for C, E, and K prophylactically
Provide blood negative for the major antigens that the patient lacks after the patient makes an antibody

hemolytic or delayed transfusion reactions, which are known to be underreported because they can manifest as a sickle cell crisis and may result in decreasing the transfusion interval.

Blood Group Disease Association

The absence of some blood group antigens and their carrier molecules can result in disease. For example, an absence of the Rh and Rh-associated glycoprotein (RhAG) proteins causes stomatocytosis[17] and anemia, termed *Rh*$_{null}$ *syndrome*. The absence of Xk protein is associated with the *McLeod syndrome*, which is associated with myopathy and neurodegeneration. RBCs and white blood cells, such as T cells, from patients with leukocyte adhesion deficiency II (also known as *congenital disorder of glycosylation type II*) lack antigens that are dependent on fucose. The RBCs have the Le(a−b−) Bombay phenotype and the white blood cells lack sialyl-Le^x, which explains the high white blood cell count and infections in these patients. Hemagglutination is a simple test that can be used to diagnose these syndromes. In patients with paroxysmal nocturnal hemoglobinuria, a proportion of the RBCs will lack antigens carried on GPI-linked proteins. Other associations between blood group antigens and diseases are summarized in Table 111.1.

Diseases associated with antibodies to blood group antigens include hemolytic disease of the newborn, warm autoimmune hemolytic anemia, cold hemagglutinin disease, and paroxysmal cold hemoglobinuria. Hemagglutination is a valuable aid in diagnosis of these conditions.

Blood Group Systems

Presented here is a brief description of the most clinically relevant blood group systems in approximate order of clinical significance. For further information and prevalence of blood group antigens in different populations, refer to specialized texts such as *Human Blood Groups*, *The Blood Group Antigen Facts Book*, and the AABB *Technical Manual*.[2,3,18]

Carbohydrate Blood Groups

ABO and H

The ABO blood group system is by far the most clinically significant, because of the presence of naturally occurring IgM antibodies (and sometimes IgG). The original observation by Landsteiner that certain human erythrocyte suspensions were agglutinated by other human sera led to the recognition of ABO polymorphism.[19] This initial observation is still the cornerstone of modern transfusion practice more than a century later.

Antigens and Their Synthesis

H antigens (ABH) occur on glycoproteins and glycolipids and are synthesized in a stepwise fashion by glycosyltransferases that sequentially add specific monosaccharides in specific linkages to a growing oligosaccharide precursor chain (reviewed in Clausen and Hakomori[20]). The terminal sugar determines antigen specificity (Fig. 111.2). Group O individuals have H antigen only, the terminal sugar of which is fucose, and this is the precursor substrate for A and B antigens. Group O individuals have defective A or B transferases. The A and B transferase enzymes differ only by the nature of the monosaccharide added to the chain. *N*-acetyl-D-galactosamine is added by A-transferase, and D-galactose is added by B-transferase. In clinical practice, four ABO phenotypes (A, B, O, and AB) are discriminated. In addition, two common variations of group A (A$_1$ and A$_2$) can be distinguished. The differences between A$_1$ and A$_2$ phenotypes are quantitative and qualitative. Not only is the A$_1$ transferase more efficient in converting H to A antigen (approximately five times more A sites per RBC on A$_1$ RBCs than on A$_2$ RBCs), it also has the capacity to make A$_1$ antigen on the repetitive A epitope. Quantitatively normal ABH expression also requires the branching of carbohydrate chains, which is performed by the blood group I enzyme. Some H antigen precursor remains on A and B RBCs in this order: $A_2 > B > A_2B > A_1 > A_1B$.

Inherited and Acquired ABH Variation. In addition to the main ABO types, there are many other inherited phenotypes with a weaker expression of the specified antigen, for example, A$_3$, A$_x$, A$_{el}$, B$_3$, B(A), and cis-AB. This can cause problems in determining the ABO blood group, but for patients needing immediate transfusion, the selection of group O red cells and AB plasma products is an option. In blood donors, if a very weak expression of A or B antigens on the RBCs is not detected, the major risk is that they may be transfused to a patient whose antibodies may cause accelerated destruction of the transfused cells.

Rare Bombay (O$_h$) phenotype RBCs, first reported in Bombay (Mumbai), India, lack H antigen and, consequently, A and B antigens. Other variants with weak H expression on RBCs, with or without H in secretions, also occur (para-Bombay) and have been reviewed.[21] Of clinical relevance, potent anti-H with the same hemolytic potential as anti-A and anti-B can be produced by Bombay individuals. Anti-H is often found in para-Bombay individuals but is generally not a potent antibody. HDFN caused by anti-H has not been reported.

Acquired B antigen is a rare phenomenon that results from the action of bacterial deacetylase, an enzyme that can remove an acetyl group from the A-terminal sugar, *N*-acetylgalactosamine. Galactosamine is similar to galactose, the B-specific terminal residue, and anti-B reagents can cross-react with the deacetylated structure. Acquired B can occur in individuals suffering from gram-negative infections of gastrointestinal origin or carcinoma and can be clinically significant if a patient's blood group is misinterpreted and group AB blood is transfused. Other polyagglutinable states (e.g., T, Tn, Tk) are detected by naturally occurring antibodies found in the serum of most people; these can be identified by a panel of lectins.

A or B antigen expression can weaken in patients with acute leukemia or stress hematopoiesis or, occasionally, during pregnancy. Chromosomal deletions or lesions that involve the *ABO* locus can result in the loss of transferase expression in the leukemic cell population. A decrease in A or B antigen expression, when found without a hematologic disorder, can be prognostic of a preleukemic state.

Genes and Enzymes. The ABO gene was cloned in 1990 following purification of A transferase; since then, over 200 different alleles have been described.[22] There are only four amino acid differences between A and B transferases in the catalytic domain, two of which (Leu266Met and Gly268Ala) are primarily responsible for the substrate specificity. The group O phenotype results from mutations in ABO that cause a loss of glycosyltransferase activity. The most common group O allele (*ABO*O1*) results from a single nucleotide deletion near the 5' end of the gene that causes a frameshift and early termination with no active enzyme production. The rare B(A) and cis-AB phenotypes have both A and B enzyme activity from a single allele caused by variant glycosyltransferases that have a combination of A-specific and B-specific residues.

The fucosyltransferases required for H synthesis are encoded by two closely linked genes on chromosome 19, *FUT1* (or H) and *FUT2* (or *Se* for secretor), which have different substrate specificity and expression in tissues. Homozygosity for defective *FUT2* alleles is responsible for the common nonsecretor phenotype in which A, B, and/or H antigen are not present in secretions. Individuals homozygous for null alleles at both the *FUT1* and *FUT2* loci have the Bombay phenotype (see earlier section).

ABO and Transplantation. As tissue antigens, ABO antigens are important in solid organ transplantation. Recipient antibodies will

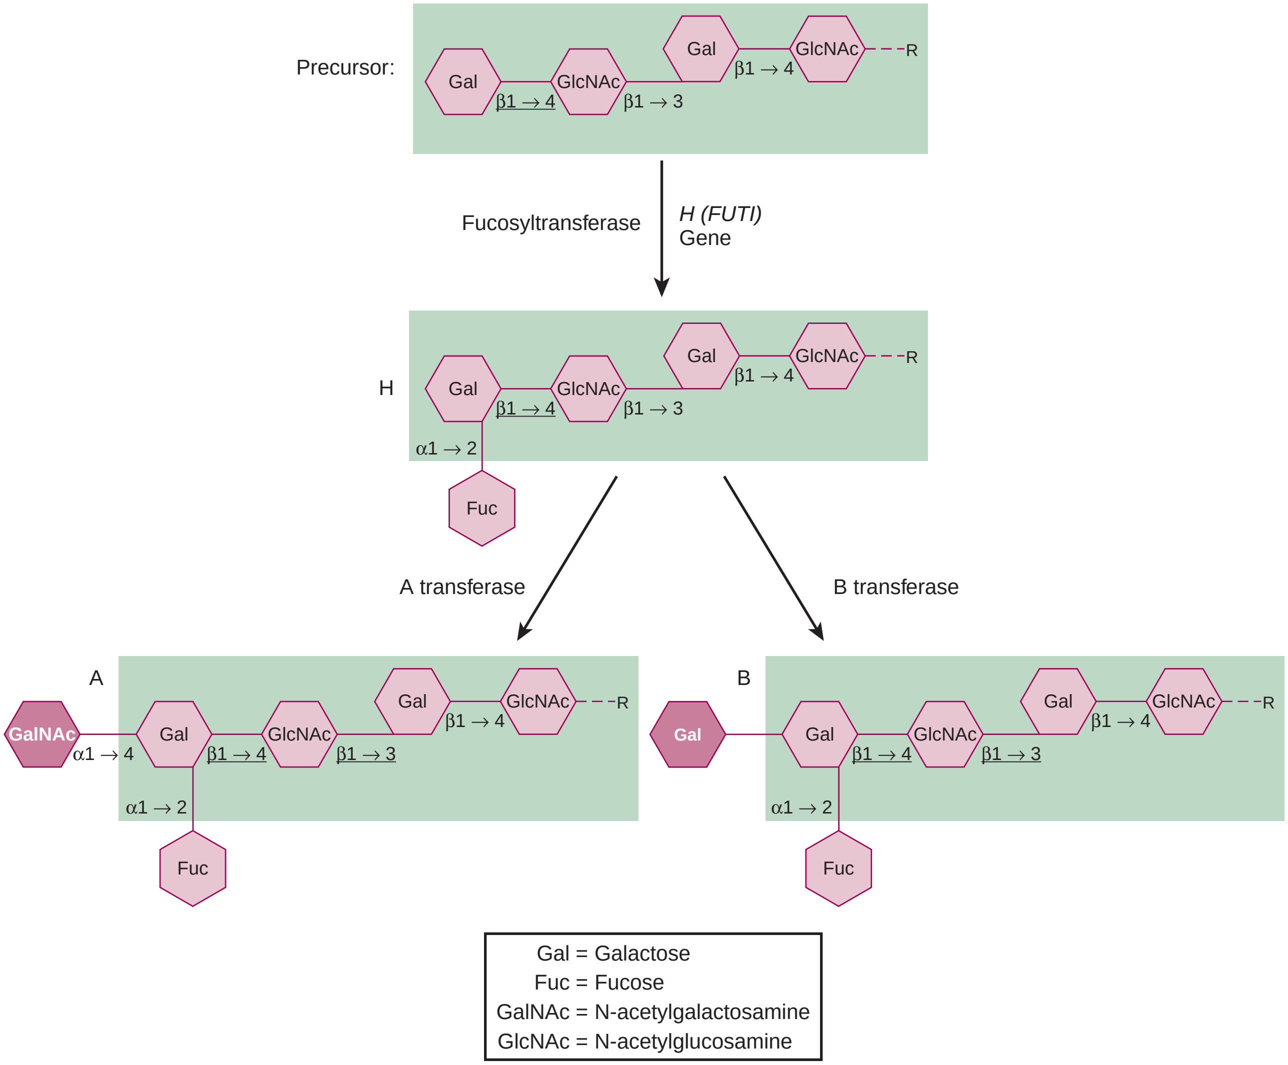

Figure 111.2 BIOCHEMICAL STRUCTURES OF ABH ANTIGENS. Schematic representation of the terminal portions of the carbohydrate structures carrying the H, A, and B antigens on red blood cells.

react with antigens on the transplanted organ and complement activation at the surface of endothelial cells can result in rapid destruction and hyperacute rejection. However, successful transplantation across ABO barriers is possible, particularly with blood group A_2 to O and with current immunosuppressive and pretreatment regiments including removal of ABO antibodies.[23] Allogeneic hematopoietic stem cell transplantations are routinely performed regardless of ABO compatibility, but occasionally initial hemolysis or pure red cell anemia because of persisting anti-A or anti-B titers in the recipient can result.

Antibodies. Anti-A and anti-B are found in the sera of individuals who lack the corresponding antigens. They are produced in response to environmental stimulants, such as bacteria. These antibodies are produced after birth, reaching a peak at 5 to 10 years of age, and declining with increasing age. The antibodies are mostly IgM and can activate complement, which in conjunction with the high density of ABO antigen sites on RBCs, are responsible for the severe, life-threatening transfusion reactions that may result following ABO-incompatible transfusions. In contrast, HDFN caused by ABO antibodies is usually mild because (1) placental transfer is limited to the fraction of IgG anti-A and anti-B found in maternal serum, (2) ABH antigens are not fully developed on fetal RBCs because of a lack of fully branched carbohydrate chains, and (3) tissue ABH antigens provide additional targets for the antibodies.

Platelets have intrinsic A, B, and H antigens; thus, ABO incompatibility can decrease the posttransfusion platelet increment, but this is often not of clinical significance.[24] However, platelets from donors with an A_2 phenotype lack both A and H antigens. Approximately 20% of group A platelets would be from A_2 donors and would be appropriate for "universal" use. Platelets from A_2 donors may also be a superior product for patients undergoing A/O major mismatch allogeneic progenitor cell transplantation.[25]

Potent anti-H (along with anti-A and anti-B) found in O_h (Bombay) individuals will destroy transfused RBCs of any ABO group, so these individuals must be transfused only with H−RBCs. In contrast, anti-H identified in individuals with low expression of H antigen, notably A_1B and A_1, is usually IgM, reacts only at lower temperatures, and is thus clinically insignificant.

Other Carbohydrate Blood Group Systems

As for all glycoconjugate structures, sequential enzymatic action is required to build other carbohydrate antigenic epitopes, and the genetic background of all these involves different glycosyltransferase loci.

The null p phenotype, P_2^k and P_1^k, are of clinical interest because of potent naturally occurring antibodies that are present in plasma of individuals whose RBCs lack the glycolipid-based antigens P1/P/P^k, P1/P/PX2, or P/PX2, respectively. In analogy with the ABO blood group system, antibodies of IgM and IgG class (anti-PP1P^k, anti-P1PPX2, or anti-PPX2) are made against the missing antigens. Although the incidence of the null phenotypes is only 5 to 10 per million, they have attracted considerable interest because of their relationship to disease and as receptors for pathogens. Women with p and P^k phenotypes suffer a high incidence of spontaneous abortion, a phenomenon most likely caused by destruction of the placenta by anti-P. In addition, anti-P and anti-P^k cause hemolytic transfusion reactions if antigen-positive RBCs are transfused. Transient autoanti-P, produced following a viral infection, causes paroxysmal cold hemoglobinuria and lysis of autologous P-positive RBC. P antigen (also known as *globoside*) is the cellular receptor for the parvo-B19 virus that causes erythema infectiosum (fifth disease) in children, sometimes complicated by severe aplastic anemia because of lysis of early erythroid precursors. P-fimbriated *Escherichia coli* expresses both P-binding and P^k-binding molecules at the tips of their pili, a finding with implications for uropathogenicity. Individuals lacking P, or P^k and P, appear to be naturally resistant to these bacterial and viral infections. In contrast to anti-P and anti-P^k, it should be noted that anti-P1 is a cold-reactive agglutinin that seldom has clinical importance. The clinical importance of anti-PX2 made by P^k individuals is unclear.

Lewis antigens are fucosylated glycolipids that are synthesized by nonerythroid cells, circulate in plasma, and are passively adsorbed onto RBC. Antibodies to Lewis can be made by individuals with the Le(a−b−) phenotype. These antibodies are of IgM class and seldom cause any clinical problems. Lewis antibodies are commonly found in pregnant women.

The i and I antigens are nonterminal epitopes on linear and branched carbohydrate structures, respectively, carrying ABH antigens at their terminal ends. During the first years of life, linear chains are modified into branched chains, resulting in the appearance of I antigens. The i phenotype is very rare among adults, but it is the normal state on RBCs from fetuses and infants. The gene encoding the I-branching β-1,6-N-acetylglucosaminyltransferase (GCNT2) has three alternative forms of exon 1 with common exons 2 and 3. Mutations in exon 2 or exon 3 silence GCNT2 and give rise to the form of the i phenotype that is associated with cataracts in Asians. Mutations in exon 1C silence the gene in erythrocytes (but not in other tissues) and lead to the i phenotype without cataracts.

Alloanti-I made by a person with the rare i adult phenotype can be clinically significant and cause destruction of transfused I-positive RBCs. However, the sera of all I-positive individuals contain autoanti-I that is clinically benign and reactive only at or below room temperature. In contrast, cold hemagglutinin disease is characterized by a high titer of complement-fixing monoclonal anti-I, which causes in vivo hemolysis and hemolytic anemia. The titer and thermal range of autoanti-I is often increased following infection with *Mycoplasma pneumoniae*. If transfusion cannot be avoided, donor RBCs should be transfused through a blood warmer.

The FORS1 blood group antigen is a rare low prevalence antigen that is A-like in that it is defined by a terminal *N*-acetylgalactosamine and was first recognized as a weak A subgroup. The antigen has been defined as Forssman antigen, commonly found on the RBCs of nonprimate mammals, and arises from a gain-of-function mutation in the *GBGT1* pseudogene. The clinical relevance of anti-FORS1 found naturally occurring in the plasma of most individuals is not known.

The blood group system Sid (symbol SID; number 038) was recently assigned to the β-1,4-N-acetylgalactosaminyltransferase (β4GalNAc-T2) encoded by the *B4GALNT2* gene. Through a combination of experimental and bioinformatics approaches, it was shown that that Sd(a−) was due to a c.1396T>C variation in the *B4GALNT2* gene leading to a likely deleterious amino acid polymorphism (p.Cys466Arg).[26]

Protein Blood Groups

Rhe, Rhe-associated Glycoprotein, and LW Blood Group Systems

The Rh system is second only to the ABO system in importance in transfusion medicine. Rh antigens, especially D, are highly immunogenic; thus in most countries, blood for transfusion is tested and labeled with the D antigen type (Rh-positive or Rh-negative) and D− recipients are transfused with D−RBC products.

TABLE 111.5 Prevalence of the Principal Rhesus Haplotypes

		Incidence (%)		
Fisher-Race Haplotype	Modified Weiner Haplotype	White	African Black	Asian
Rh-Positive				
DCe	R_1	42	17	70
DcE	R_2	14	11	21
Dce	R_0	4	44	3
DCE	R_Z	<0.01	<0.01	1
Rh-Negative				
ce	r	37	26	3
Ce	r′	2	2	2
cE	r″	1	<0.01	<0.01
CE	r^y	<0.01	<0.01	<0.01

Three systems for naming Rh antigens have been used. Two are shown in Table 111.5, which indicates the incidence of the common Rh haplotypes present in different ethnic groups. The Fisher-Race nomenclature was based on the premise that there were three closely linked genes (D, C/c, and E/e), whereas the Wiener nomenclature (Rh-Hr) was based on the belief that a single gene encoded multiple factors (antigens). Although it is now well established that two genes, the *RHD* and *RHCE*, encode the Rh proteins, the Fisher-Race (D, C/c, and E/e) terminology is often preferred for written communication; for spoken communication, a modified version of the Wiener nomenclature is preferred. Uppercase *R* indicates that D antigen is present and use of a lowercase *r* (or "little r") indicates that it is absent. The C or c and E or e antigens carried with D are represented by subscripts: 1 for Ce (R_1), 2 for cE (R_2), 0 for ce (R_0), and Z for CE (R_z). The presence of these antigens without D is represented by a superscript: prime for Ce (r′), double-prime for cE (r″), and y for CE (r^y). This terminology allows one to convey the common Rh antigens (the phenotype) with a single term. The third system of numeric designations is not widely used in the laboratory, with a few exceptions (Rh17, Rh32, Rh33).

Genes, Proteins, Antigens, and Phenotypes. The Rh proteins are designated RhD (encoded by RHD), which carries the D antigen, and RhCE (encoded by RHCE), which carries the CE antigens (either ce, cE, Ce, or CE). RhD differs from the various forms of RhCE by 32 to 35 amino acids. RhD and RhCE are not glycosylated but form a complex in the RBC membrane with RhAG (Rh-associated glycoprotein). Other proteins present in the Rh-complex are CD47 (an integrin-associated protein), Lansteiner-Wiener (LW) proteins, and glycophorin B. The Rh-complex also associates with band 3 (the anion exchanger) as a macrocomplex in the membrane.

The D-negative (Rh-negative) phenotype is prevalent in Whites (15% to 17%), less common in African Blacks (3% to 5%), and rare in Asians (<0.1%). The absence of D in Europeans is primarily caused by a deletion of the *RHD* gene. African Blacks, and rare D-negative Whites and Asians carry a *RHD* gene that is silenced by a variety of molecular events.[7]

RBCs with weak D have D antigen but at lower levels than normal because of one or more amino acid changes that are often predicted to be in the intracellular or transmembrane regions of RhD. The RBCs do not lack, or have altered, epitopes of D. Many individuals with a serologic weak D phenotype have weak D types 1, 2, and 3 by *RHD* genotyping, and individuals with these genotypes can safely receive D-positive blood and do not make clinically significant anti-D.[27,28]

Partial D antigens (previously called *D categories* or *D mosaics*) are caused either by point mutations in *RHD* that encode amino acid changes that alter D epitopes, or by replacement of *RHD* nucleotides or exons by the equivalent part of *RHCE* that result in loss of D

WEAK OR VARIABLE D-TYPING

Clinically significant D-sensitization potentially results in a pregnancy with a fetus at risk for hemolytic disease of the fetus and newborn and hemolytic transfusion reactions if transfused with D-positive red blood cells (RBCs). Individuals with RBCs that express a partial D antigen are at risk for D-sensitization, whereas those with weak D antigen are usually not at risk. These cannot be distinguished by serologic reactivity, because either may present as weak or moderately positive or give variable results with anti-D reagents. Particularly in the prenatal setting, *RHD* genotyping should be done to distinguish weak D from partial D. Women with weak D expression, particularly weak D types 1, 2, and 3, are not at risk for clinically significant D-sensitization and therefore are not candidates for RhIG prophylaxis. In contrast, individuals with partial D, lack D epitopes and have produced clinically significant anti-D and should receive RhIG prophylaxis. *RHD* genotyping avoids unnecessary treatment with RhIG and excess use of Rh-negative blood in patients with weak D antigen.

TRANSFUSION MANAGEMENT OF PATIENTS WITH WARM AUTOIMMUNE HEMOLYTIC ANEMIA

Patients with warm autoimmune hemolytic anemia may present with jaundice, fatigue, and anemia, or they may show no overt clinical manifestations. The antibody screen and antibody identification panel will show all red blood cells (RBCs) positive (panagglutinin) with anti-IgG in the indirect antiglobulin test. The autocontrol (patient's own plasma and RBCs) will also be positive.

History: A transfusion history should be obtained to differentiate these results from a hemolytic transfusion reaction or hemolysis because of an alloantibody.

DAT: A direct antiglobulin test should be performed with anti-IgG and anti-C3. In clinically significant hemolysis, the DAT is usually strongly positive.

Eluate: If patient has been recently transfused (3–4 months), an eluate should be prepared from the patient cells to remove the antibody(ies); the eluate should be tested to determine specificity. The eluate is usually reactive with all cells when tested by the IAT with anti-IgG.

Phenotype or genotype: Type the patient's RBCs for minor blood group antigens (Cc, Ee, K, Jka/b, Fya/b, Ss) if the patient has not been recently transfused. When possible, IgM typing reagents are used because the patient's own antibody-coated RBCs may result in false-positive typing. Some laboratories are able to remove the IgG from the RBCs and perform a phenotype, but alternatively, genotyping for minor blood group antigens including $\text{Do}^{a/b}$ antigens (there is no serologic reagent) can be performed.

Adsorption: Adsorb the serum autoantibody onto the patient's own RBCs to test for underlying alloantibody if the patient has not been recently transfused (3–4 months). If the patient has been recently transfused or if the low hematocrit results in insufficient autologous RBCs, perform alloadsorption with well-characterized RBCs (usually three with known antigen profiles). Test the adsorbed serum for underlying alloantibodies.

Crossmatch: Perform with neat and with adsorbed plasma. Crossmatch performed with neat plasma will usually be incompatible.

Communication: Inform ordering physician of reactivity and of delay in receiving crossmatched RBCs. Provide emergency-release RBCs if patient's clinical situation warrants. Inform the physician that the patient may hemolyze transfused RBCs similar to hemolysis of his or her own RBCs.

Transfusion: Consider providing RBC units negative for minor antigens that the patient also lacks. Consider matching for Cc, Ee, K, Jka/b, Fya/b, Ss (and Doa/b if possible). This potentially enables RBC units to be available before completion of the antibody identification testing. Transfusion with antigen-matched units potentially allows continued transfusion without need for autoadsorption or alloadsorption unless signs and symptoms of RBC destruction occur or there is a change in reactivity in antibody screening or the DAT.

epitopes. RBCs with a partial D antigen may have strong or weak reactivity with anti-D. Because patients with partial D antigens can make anti-D directed to the D epitopes that are altered or absent, they ideally should receive D-negative blood and women of childbearing potential are candidates for Rh immune globulin. In practice, many type as D-positive and are recognized only after they make anti-D. However, in the United States monoclonal D typing reagents licensed by the Food and Drugs Administration for patient testing classify partial Rhesus antigen D category VI (DVI) phenotypes as D-negative in direct testing, and as D-positive by IAT. *RHD* genotyping is very useful to distinguish weak D phenotypes from partial D to guide selection of blood for transfusion and prevent D alloimmunization and to avoid unnecessary Rh immune globulin injection (see box on Weak or Variable D Typing). Several phenotypes, including D− −, Dc−, and $DC^{w}-$, have an enhanced expression of D antigen and no, or variant, CE antigens. They are caused by replacement of portions of *RHCE* by *RHD*. The RhD sequences in RhCE, along with a normal RhD, explain the enhanced D and account for the lack, or reduced expression, of CE antigens. Immunized individuals with these CE-depleted phenotypes can make antibodies to high-prevalence Rh antigens.

C and c antigens differ by four amino acids, but only residue Ser103Pro is predicted to be extracellular. E and e differ by one amino acid, Pro226Ala. The RhD and various combinations of RhCE proteins (ce, Ce, cE, and CE) are typical for the majority of White transfusion recipients. However, Rh proteins in other ethnic groups often carry additional polymorphisms, particularly in individuals of African descent, and this fact often complicates transfusion in patients with sickle cell disease. For example, the RBCs of more than 30% of Blacks are VS+ because of a Leu245Val substitution in Rhce, and expression of this antigen is associated with variant expression of e antigen. Many other amino acid changes in Rhce, as well as in RhD, are associated with production of Rh antibodies in patients with sickle cell disease. RH genotyping by DNA methods allows enhanced Rh antigen matching of patients and donors and is particularly important in patients who present with Rh antibodies reacting with all, or the majority, of cells tested.

The Rh_{null} phenotype is very rare and occurs on two genetic backgrounds: the "regulator" type, caused by mutations in *RHAG*, which encodes an Rh-associated glycoprotein, and the "amorph" type, caused by mutations in *RHCE* on a D− (deleted *RHD*) background. Rh_{null} RBCs are stomatocytic, fragile, and associated with anemia. RhAG is involved in maintenance of cation balance in RBCs.[17]

Antibodies. Most Rh antibodies are IgG and do not activate complement. As a result, primarily extravascular hemolysis, rather than intravascular hemolysis, occurs in transfusion reactions involving Rh antibodies. The antibodies are almost always caused by RBC immunization from pregnancy or transfusion and usually persist for years. Anti-D can cause severe hemolytic transfusion reactions and HDFN, but the incidence of anti-D has decreased with the prophylactic use of Rh immune globulin. Most Rh antibodies should be considered as having the potential to be clinically significant for HDFN and hemolytic transfusion reactions. If serum antibody levels fall below detectable levels, subsequent exposure to the antigen characteristically produces a rapid secondary immune response. Autoantibodies in the sera of patients with warm autoimmune hemolytic anemia, as well as in some cases of drug-induced autoimmune hemolytic anemia, appear to demonstrate relative specificity to high-prevalence Rh antigens, although specificity for other members of the Rh complex have not been ruled out (see box on Transfusion Management of Patients With Warm Autoimmune Hemolytic Anemia).

RHAG Blood Group System

RhAG glycoprotein, encoded by *RHAG*, is highly similar to the RhD and RhCE proteins. It carries four blood group antigens: two of high prevalence (RHAG1 and 3) and two of low prevalence (RHAG 2 and 4). Antibodies to RHAG4 cause HDFN. RhAG is important for erythrocyte ion balance in RBCs and is required for the expression of RhD and RhCE proteins forming the core of the Rh-complex.

Lansteiner-Wiener Blood Group System

Rh and LW are independent blood group systems but have a phenotypic relationship. In adults, D-positive RBCs have a stronger expression of LW antigen than D-negative RBCs, and anti-LW can be confused with anti-D. Transient loss of LW antigens from RBCs has been described in pregnancy and in patients with diseases, particularly Hodgkin disease, lymphoma, leukemia, sarcoma, and other forms of malignancy. Loss of LW antigens is usually associated with the production of antibodies that appear to be alloanti-LW.

Kell and Kx Systems

The Kell glycoprotein is highly folded through multiple intrachain disulfide bonds and is covalently linked to the XK protein in the RBC membrane. Kell is highly polymorphic because of single amino acid substitutions in the glycoprotein that account for 35 of 36 antigens described to date. The K antigen is remarkably immunogenic even though it differs from wild-type (k, small k) by only one amino acid, and it appears that loss of an *N*-glycan exposes the peptide, thereby rendering it immunogenic.

Inherited weak expression of Kell antigens, termed K_{mod} phenotype, occurs with amino acid changes in the protein, with Kp^a in cis, and in the McLeod phenotype. Transient depression of Kell system antigens may also occur in autoimmune hemolytic anemia, in microbial infections, and was reported in two cases of idiopathic thrombocytopenia purpura. The lack of Kell antigens (the K_0 or K_{null} phenotype) is caused by multiple different gene defects.

HDFN caused by anti-K can result in severe neonatal anemia, and unlike anti-D, maternal antibody titers and amniotic bilirubin levels are not good predictors of the severity of the disease. Kell antigens are expressed very early during erythropoiesis, and anti-K has been shown to suppress erythropoiesis in vitro. This may explain the low level of bilirubin observed in cases of neonatal anemia; thus Doppler screening of the fetal middle cerebral artery peak systolic velocity is used to monitor anemia. Other unusual consequences of Kell antibodies include risk for fetal thrombocytopenia and neutropenia.

McLeod Syndrome. This uncommon syndrome is associated with the loss of expression of Kx protein caused by mutations and deletions in the *XK* gene. The syndrome, which is X-linked and manifests only in males, may be underdiagnosed. The physical characteristics, which often develop only after the fourth decade of life, include muscular and neurologic problems. A minority of patients with chronic granulomatous disease also have the McLeod phenotype as a result of X-chromosome deletions encompassing both genes. Carrier females have two populations of RBCs (one of the McLeod phenotype and one of normal phenotype).

Duffy Blood Group System

The Duffy blood group protein, Atypical chemokine receptor 1, is a promiscuous chemokine receptor found on RBCs and on endothelial cells in the kidney and brain that binds a family of chemotactic and proinflammatory peptides from the CXC (IL-8, MGSA) and the CC (RANTES, MCP-1, MIP-1) classes. The physiologic role of FY is clear, but on RBCs the receptor may allow RBCs to act as scavengers for excess chemokines. FY is also a receptor to which *Plasmodium vivax* merozoites can bind to invade RBC and cause malaria.

Antigens. The Fy^a and Fy^b antigens differ by a single amino acid (Gly42Asp) located on the N-terminal extracellular domain of the FY glycoprotein and is responsible for the common Fy(a+b−), Fy(a−b+), and Fy(a+b+) phenotypes. The null Fy(a−b−) phenotype is rare in most ethnic groups, but it is common in people of African and Arabian origins. The null phenotype most often results from a mutation in the promoter region of FY that disrupts a binding site for the erythroid transcription factor GATA-1 and results in loss of FY on RBCs. Because the erythroid promoter controls expression only in erythroid cells, FY expression in other tissues is unaffected. All individuals of African origin with a mutated GATA box to date have been shown to carry FYB and therefore Fy^b is expressed on nonerythroid tissues. This explains why Fy(a−b−) individuals make anti-Fy^a but not anti-Fy^b. Fy(a−b−) caused by a mutated GATA box on an FYA allele has been found in Papua New Guinea, another malaria-endemic region.

Antibodies. FY antigens are much less immunogenic than Rh and K. Anti-Fy^b is less common than anti-Fy^a, and both antibodies can cause delayed hemolytic transfusion reaction (DHTR) and rarely HDFN. Anti-Fy3 is made by Fy(a−b−) individuals who are exceptions to above, and it is speculated they may lack FY protein on all cells.

Kidd Blood Group System

The Kidd (JK) blood group protein was implicated in urea transport when RBCs lacking the antigens were shown to resist lysis in 2 M urea. The protein is present in RBCs and kidney medulla and is a constitutive urea transporter, but failure to express Kidd does not result in an overt clinical syndrome; the only observed manifestation is a reduced capacity to concentrate urine.

Antigens. The Jk^a and Jk^b antigens differ by a single amino acid (Asp280Asn) and are responsible for the common Jk(a+b−), Jk(a−b+), and Jk(a+b+) phenotypes. The Jk(a−b−) or Jk_{null} phenotype is uncommon and occurs with greater incidence in Polynesians, Asians, and Finns. Many different molecular changes in both JK antigen A (JKA) and JK antigen B (JKB) alleles have been shown to abolish expression of the Kidd blood group protein. Weakly expressed variants of Jk^a and Jk^b antigens are also not uncommon.

Antibodies. JK antibodies are responsible for at least one-third of cases of DHTR. The antibodies often drop to undetectable levels or react only with cells that are homozygous for the antigen and escape detection in the sensitized patient's serum before transfusion. JK antibodies only rarely cause HDFN, and if they do, it is typically not severe. Anti-Jk3, sometimes referred to as anti-Jk^{ab}, is produced by Jk(a−b−) individuals, and rare donors must be located for transfusion.

MNS System

M and N antigens from the MNS antigen system (MNS) are carried on alternative forms of glycophorin A (GPA/GYPA), whereas S and s antigens are carried on alternative forms of glycophorin B (GPB/GYPB). M/N and S/s are homologous proteins encoded by adjacent genes and consequently show linkage disequilibrium in inheritance of the antigens. The MNS system is highly polymorphic and most of the antigens are the result of amino acid substitutions or rearrangements between *GYPA* and *GYPB*. Persons who are S−s− are usually of African origin. They either also lack the high-prevalence U antigen arising from a deletion of *GYPB* or express variant weak U antigen as a result of an altered form of *GYPB*.

Antibodies. Anti-S, anti-s, and anti-U are usually IgG and can be clinically significant antibodies. Anti-M and anti-N can be naturally occurring, may be reactive at room temperature or below, and are often clinically insignificant.

Other Protein Antigens

Antibodies to antigens in the following systems are less common than those described earlier in this chapter, and information regarding their general clinical significance is summarized in Table 111.3.

Lutheran System

Lutheran (Lu), along with Secretor, provided the first example of autosomal linkage in humans, the first example of autosomal crossing over, and the first indication that crossing over in humans is more common in females than in males. The Lu system consists of four antithetical pairs of antigens and 16 independent high-prevalence antigens. The Lu(a−b−) phenotype is rare, but in the majority of individuals, it is caused by heterozygosity for silencing mutations in the *EKLF/KLF1* gene. KLF1 is a transcription factor that regulates many erythroid-specific genes, and the expression of antigens in other blood group systems (e.g., Kn, In) is also affected. In one family, heterozygosity for a mutation in the *GATA1* gene was shown to be responsible for the Lu(a−b−) phenotype.

Antibodies. Antibodies in this system are rarely encountered because the antigens are not highly immunogenic. They are usually IgG and give characteristic agglutinates surrounded by unagglutinated RBCs. They can cause mild transfusion reactions, but do not typically cause HDFN. Anti-Lu3 is found in the serum of immunized people of the rare recessive Lu(a−b−) phenotype, and the antibody is usually IgG and may cause DHTR or HDFN. Blood with the Lu(a−b−) phenotype should be used for transfusion of patients with these antibodies.

Diego System

The Diego (Di) blood group antigens are on Band 3 anion transport protein (AE1), one of the most abundant erythrocyte glycoproteins. AE1 forms complexes with many other proteins in the cell membrane and is important for RBC stability. The Diego blood group system contains three antithetical pairs of antigens and 16 low-prevalence antigens. Di^b antigen has a prevalence of greater than 99.9%, but Di^a is rare in most populations. Exceptions include Indigenous South Americans (Di^a occurs in 54% of this population) and Native Americans, approximately 12% of whom are Di(a+).

Antibodies. Di antibodies are usually IgG and do not bind complement. These antibodies have caused DHTR (usually delayed) and HDFN. Autoantibodies to band 3 are common in patients with warm autoimmune hemolytic anemia.

Yt Blood Group System

The Yt system was named in 1956 when an antibody was found in the serum of patient whose last name was Cartwright. Yt^a occurs with a prevalence of more than 99% in random blood samples, and Yt^b is found with a prevalence of approximately 8%, except in Israelis, in whom it has a prevalence of 20% or higher.

Antibodies. Yt antibodies usually are IgG and do not bind complement. These antibodies have caused DHTR but not HDFN.

Scianna Blood Group System

The Scianna (Sc) antigens are expressed by the RBC adhesion protein, erythrocyte membrane-associated protein. Sc1 is a high-prevalence antigen (prevalence ≈99.9%), and Sc2 is a low-prevalence antigen (1%); there are five other Scianna antigens.

Antibodies. Sc antibodies are usually IgG, and some bind complement. These antibodies have not caused DHTR, and although they have caused a positive DAT in cord RBCs, they have not caused HDFN. Several examples of autoanti-Sc1 have been reported, some reactive in tests using patient serum but not plasma. Autoanti-Sc3–like antibodies have been described in one patient with lymphoma and in one patient with Hodgkin disease whose RBCs had suppressed Sc antigens.[2]

Dombrock Blood Group System

Dombrock (Do) antigens are carried on a GPI-linked glycoprotein that is a member of the mono-ADP-ribosyltransferase family, although Do has no demonstrable enzyme activity on the RBC. The Do blood group system consists of two antithetical antigens, Do^a and Do^b, and eight other antigens of high prevalence. The null phenotype is Gy(a−).

Antibodies. Do^a and Do^b antigens are poor immunogens, and anti-Do^a and anti-Do^b are rarely found as single specificities. Antibodies in the Do system are usually IgG and do not bind complement. These antibodies have caused DHTR and a positive DAT but no clinical HDFN.

Colton Blood Group System

The Colton (Co) antigens are carried on aquaporin-1 (AQP-1), the first water channel protein characterized in mammals, and are also found in the kidney. The function of AQP-1 in RBCs may be to rehydrate rapidly after shrinking in the hypertonic environment of the renal medulla. Co^a has a prevalence of 99.9%, its antithetical antigen Co^b has a prevalence of 10%, and Co3 and Co4 are present on all RBCs except those of the very rare Co(a−b−) null phenotype. Apparently healthy propositi with the Co(a−b−) phenotype and AQP-1 deficiency have RBCs with an 80% reduction in the ability to transport water. The residual water transport in these RBCs may be through another member of the water channel protein family, AQP-3, which transports water, glycerol, and urea, and carries the blood group antigen aquaporin 3 (AQP3/GIL).

Antibodies. Antibodies in the Co system are usually IgG and some bind complement. The antibodies have caused DHTR and HDFN.

Gerbich Blood Group System

The Gerbich system antigens are carried on glycophorin C (GPC) and glycophorin D (GPD). There are six high-prevalence antigens and five low-prevalence antigens. The two glycoproteins are products of the *GYPC* gene. The gene consists of four exons, and the smaller GPD is generated by the use of an alternative translation initiation site.

Antibodies. The antibodies may be immune or naturally occurring. Most are IgG and some of these bind complement. Some antibodies may be IgM. Although some antibodies have caused DHTR, others have been benign. Anti-Ge3 has caused HDFN, and similar to Kell antibodies, the disease is associated with severe anemia. Clinical HDFN associated with anti-Ge2 has not been reported, but the antibodies have been eluted from DAT-positive cord RBCs.

Cromer Blood Group System

The Cromer (Cr) antigens are carried on decay-accelerating factor (DAF, CD55), a complement control protein attached to the RBC membrane through GPI-linkage. Cr is a system of two sets of antithetical antigens (Tc^a/Tc^b/Tc^c and WES^a/WES^b), 16 high-prevalence antigens, and three low-prevalence antigens. The Cr(a−) phenotype is the least rare of the negative phenotypes, and with the exception of one Spanish-American woman, all people with Cr(a−) RBCs are Black. Most of the other phenotypes are exceedingly rare.

Antibodies. Antibodies in the Cr system are usually IgG and do not bind complement. The antibodies have caused mild DHTR but not HDFN.

Knops Blood Group System

The Kn blood group antigens are carried on complement receptor 1 (CR1). Kn^a, Sl^a, and McC^a antigens are fairly common and have a similar prevalence (>90%) in different populations; however, Sl^a is present on RBCs of 98% of Whites, but on only 60% of African Americans. Typing for Kn system antigens can be challenging because the low level of expression on the RBCs in some disease processes gives false-negative results. RBC CR1 is important in the processing of immune complexes, binding them for transport to the liver and spleen for removal from the circulation. The CR1 copy number per RBC (and thus antigen strength) is reduced in SLE, cold agglutinin disease, paroxysmal nocturnal hemoglobinuria (PNH), hemolytic anemia, insulin-dependent diabetes mellitus, acquired immunodeficiency syndrome, some malignant tumors, and any condition associated with increased clearance of immune complexes. CR1 (the Sl^a antigen in particular) may act as a receptor for the malarial parasite *Plasmodium falciparum*; thus the Sl(a−) phenotype may provide selective advantage.

Antibodies. Antibodies in the Kn system are usually IgG, and they do not bind complement. The antibodies do not cause DHTR or HDFN, and once identified, they can usually be ignored for clinical purposes. Identification may be complicated by the fluctuation of antigen expression on RBCs. In the Kn system, anti-Kn^a is the most common antibody in Whites, and anti-Sl^a is the most common in African Americans.

Indian Blood Group System

The antigens of the In system are carried on CD44. CD44 has a diverse range of biologic functions involving cell-cell and cell-matrix interactions in cells other than RBCs. It is an adhesion molecule in lymphocytes, monocytes, and some tumor cells. CD44 binds to hyaluronate and other components of the extracellular matrix and is also involved in immune stimulation, as well as signaling between cells. In^b is a common antigen, and In^a is rare in White persons but has a prevalence of 4% in the population of India, 10% in Iranians, and nearly 12% in Arabs.

Antibodies. Antibodies in the Indian system are usually IgG and do not bind complement. Some antibodies may directly agglutinate RBCs, but the reactivity is greatly enhanced by the IAT. These antibodies have caused decreased RBC survival and a positive DAT in the neonate, but not HDFN. A severe DHTR caused by anti-In^b has been reported.

Chido/Rodgers Blood Group System

Although the Ch and Rg antigens are readily detected on RBCs, they are located on the fourth component of complement (C4), which becomes bound to RBCs from the plasma. In complement activation through the classic pathway, C4 becomes bound to the RBC membrane and undergoes further cleavage; ultimately, a tryptic fragment, C4d, remains on the RBC. This C4d glycoprotein carries the Ch/Rg blood group antigens. The antigens are stable in stored serum or plasma, and the phenotypes of this system are most accurately defined in plasma by agglutination inhibition tests.

Antibodies. Antibodies in the Ch/Rg system are usually IgG, do not activate complement, and are considered benign. Considerable variation may be common in the reaction strength obtained with different RBC samples. Although these antibodies do not generally cause DHTR, they have caused anaphylactic reactions. The antibodies have not caused HDFN.

Jr Blood Group System

The Jr^a antigen is carried on ABCG2, a member of the ATP-binding cassette family of multipass membrane proteins. The protein is broadly distributed and is a high-affinity urate transporter. It is also involved in porphyrin transport and in multidrug resistance in some cancers. The Jr(a−) phenotype is the null phenotype and Jr(a−) individuals lack the protein. Many different mutations have been identified for this phenotype although it is more common among Japanese people (where it is associated with gout) and the Roma population in Europe.

Antibodies. Anti-Jr^a are usually IgG, do not activate complement and do not generally cause DHTR or HDFN, however two cases of severe HDFN have been reported.

Lan Blood Group System

Lan is carried by an ATP-binding cassette protein, ABCB6, a protein that is widely expressed. It is highly expressed in fetal liver and upregulated during erythropoiesis. ABCB6 is important in heme synthesis and transports heme, and porphyrins into the mitochondria. The Lan− phenotype is the null phenotype and it arises from many different molecular backgrounds, but is not associated with a disease phenotype.

Antibodies. Anti-Lan are generally IgG and do not bind complement but have caused mild to severe DHTR and mild HDFN.

Vel Blood Group System

The Vel blood group antigen is dependent on the SMIM1 protein for expression and a 17-bp mutation in the *SMIM1* gene accounts for the vast majority of Vel− individuals and absence of SMIM1. The protein is widely expressed but more highly expressed on erythrocytes, salivary glands, and testes, although its function is unknown. Vel antigen expression is variable on RBCs.

Antibodies. Anti-Vel are often a mixture of IgM and IgG and readily bind complement. While HDFN caused by anti-Vel is rare, the antibodies can cause severe hemolytic transfusion reactions.

CD59 Blood Group System

An antibody in the plasma of a young patient with CD59 deficiency qualified CD59 as a blood group antigen. CD59 is a GPI-linked protein on the erythrocyte and is important in complement regulation. It inhibits the formation of the membrane attack complex (MAC) by specifically binding to C8 and C9. Like other GPI-linked proteins, it is absent from the erythrocytes of PNH patients and its absence is the underlying cause of hemolysis.

Antibodies. Only one example of the antibody has been reported. It was clinically benign although a positive DAT was observed following one of the transfusions.

Augustine Blood Group System

The At(a−) phenotype in individuals of African origin is defined by an amino acid polymorphism on SLC29A1 (p.Glu391Lys), while the At(a−) members of a rare family affected by bone malformation lacked the protein due to an inactivating mutation in the *SLC29A1* gene: c.589+1 G>C. The antigen defined by the antibody produced by the null phenotype was named AUG1, and the antigen defined by the amino acid Glu391 (At^a) was named AUG2.

Antibodies. Anti-At^a are mostly IgG although may contain IgM. While HDFN due to anti-At^a is rare, the antibodies can cause severe hemolytic transfusion reactions.

KANNO Blood Group System

The blood group system KANNO (symbol KANNO; number 037) was recently assigned to the prion protein (PrP) encoded by the *PRNP* gene. Through a combination of genome-wide association studies and whole exome sequencing which showed that KANNO− was due to a c.655 G>A variation leading to the amino acid polymorphism (p.Glu219Lys).[29]

Antibodies. Anti-KANNO are mostly IgG. Anti-KANNO was first identified in a Japanese woman who was never transfused, but had a history of two deliveries.[30] Although anti-KANNO appears to be stimulated by pregnancy, it has not been reported to cause hemolytic disease of the fetus and newborn or hemolytic transfusion reactions.

CHAPTER 112

PRINCIPLES OF RED BLOOD CELL TRANSFUSION

Robert A. DeSimone, Paul M. Ness, and Melissa M. Cushing

The clinical practice of transfusion medicine has evolved substantially since the discovery of the ABO system around 1900. Two technological advances set the stage for clinical practice through blood component therapy. First, the introduction of a safe and effective anticoagulant-preservative solution (suggested by Loutit and Mollison) allowed for the preservation of blood products. Second, in the mid-1960s, the introduction of plastic blood bags by Walter and Murphy, combined with the ability to store blood for extended periods, created opportunities to use transfusions in varied clinical settings. With these discoveries, the era of modern component therapy began. In 2017, approximately 12.2 million units of whole blood/red blood cells (RBCs) were transfused in the United States. This chapter reviews appropriate RBC transfusion practice in a variety of clinical settings, the clinical implications of RBC storage, the pathogenesis of red cell alloimmunization, and existing and emerging alternatives to allogeneic RBC transfusions.

RED BLOOD CELL COMPONENTS

Modern transfusion medicine practice aims to provide the specific component of blood required, rather than whole blood: red cells for oxygen-carrying capacity, plasma for coagulation proteins, and platelets for microvascular bleeding. The component therapy approach allows for optimal use of a limited community resource (Table 112.1). Today, the clinician wishing to increase the patient's oxygen-carrying capacity is more likely to use an RBC concentrate than whole blood, although there may still be situations in which whole blood, if available, is appropriate. For particular clinical applications, several modifications can be made to RBC products to render them leukocyte-or plasma-depleted. RBCs can also be frozen for long-term storage.

Whole Blood

A unit of whole blood is collected in citrate phosphate dextrose adenine (CPDA)-1 anticoagulant, giving it a shelf-life of 35 days and a volume of approximately 510 mL (450 mL of blood plus 63 mL of CPDA-1). Within 24 hours of collection, the granulocytes are dysfunctional, and several plasma coagulation factor levels including factors V and VIII have fallen. Although clinicians have been taught that refrigerated whole blood stored has no functional platelets, evolving studies have demonstrated in vitro that platelet quantities and function are maintained for 10 to 14 days at 4°C after collection, leading to renewed interest in the use of whole blood for resuscitation.

Whole blood has the advantage of correcting simultaneous deficits in oxygen-carrying capacity, coagulation factor deficiencies, and blood volume. Therefore, whole blood is useful in the management of trauma or in surgical cases involving extensive blood loss. In this setting, whole blood has two distinct advantages: (a) it provides colloid osmotic pressure and coagulation factors not supplied by crystalloid solutions and (b) it does not expose the recipient to RBCs and plasma from different donors.

There has been recent renewed interest in fresh whole blood for patients with severe coagulopathy and shock. Few prospective trials have compared fresh whole blood with component therapy. The potential advantages for fresh whole blood are a relative increase in hemoglobin (Hb) concentration, coagulation factors, and platelets compared with component therapy. In addition, fresh products avoid some of the negative effects of storage and processing. A Food and Drug Administration (FDA) approved platelet-sparing leukocyte reduction filter is available for fresh whole blood. However, the use of fresh whole blood is limited due to the lack of published randomized controlled studies on specific indications and demonstration of significant clinical benefits, as well as logistical considerations such as wastage. The methods to achieve adequate pathogen removal and the determination of optimal storage conditions for whole blood products are the subjects of active investigations.

There has also been recent interest in the use of stored, low-titer group O whole blood (LTOWB) for civilian trauma building on successful military experience. "Low-titer" refers to low titers of anti-A (and sometimes anti-B as well) which are found in the plasma component of whole blood and may cause hemolysis of the recipient's RBCs, but a universal testing process and titer threshold to define low-titer has not been established. LTOWB can be used if a recipient's ABO group is unknown at the time of transfusion, but every local institution must adopt policies to define specific patient populations eligible to receive LTOWB and establish monitoring for potential hemolysis. Monitoring may involve regular post-transfusion hemolysis labs as well as clinical assessment of hemolysis symptoms, which are often non-specific (i.e., fever, back pain).

Increasingly studies in trauma patients have demonstrated a benefit to the early use of increased ratios of plasma and platelets to RBCs. The PROPPR study found there was a significant reduction in the time to hemostasis and a reduction in death by exsanguination within 24 hours for patients receiving a 1:1:1 ratio of RBC:plasma:platelets versus a 2:1:1 ratio. In addition, the PAMPer trial demonstrated a significant 30-day survival benefit in patients administered pre-hospital thawed plasma relative to standard-care resuscitation.

Red Blood Cells

RBCs (also referred to as *packed RBCs* or *RBC concentrates*) are obtained from anticoagulated whole blood after removal of most of the platelet-rich plasma for the production of frozen plasma or platelets, or both. At most blood centers, the RBCs are then mixed with 100 mL of an additive nutrient solution that extends the storage period to 42 days and results in flow properties similar to those of whole blood.

RBCs are the product of choice for the correction of an isolated defect in oxygen-carrying capacity, as in cases of chronic anemia. In addition, RBCs rather than whole blood are most commonly used for the emergent transfusion of patients of unknown ABO type. The use of concentrated group O RBCs without plasma containing anti-A and anti-B can minimize potential hemolysis of the recipient's red cells.

Leukocyte-Reduced Red Blood Cells

Leukocyte-reduced RBCs (LRRCs) can be prepared by a variety of methods, resulting in differing degrees of white blood cell (WBC) removal. Currently, the most widely used method of leukoreduction is pre-storage filtration that is performed at blood collection facilities after collection using blood bags with in-line filters. The various filters on the market result in greater than 99% leukocyte reduction while depleting less than 10% of the red cells.

TABLE 112.1 Red Blood Cell Components: Characteristics and Indications

Component	Characteristics	Indications
Whole blood	High volume; good flow	Combined red cell/volume deficit (massive hemorrhage; exchange transfusion)
RBCs	Lower volume Higher hematocrit	Red cell deficit
Leukocyte-reduced RBCs	Good flow in AS-1	Prevention of febrile reactions Reduction of alloimmunization Reduction of immunomodulatory effects
Washed RBCs	Plasma depletion Must use within 24 h	Prevention of severe allergic reactions Prevention of anaphylaxis in IgA deficiency
Frozen RBCs	Long-term storage Plasma and leukocyte depletion Must use within 24 h of thawing	Rare donor unit storage Autologous storage for postponed surgery

Ig, Immunoglobulin; *RBC*, red blood cell.

The major indication for the use of LRRCs is the prevention of the febrile nonhemolytic transfusion reaction, a common adverse effect of transfusion, particularly in multiply transfused patients or multiparous females. These reactions are believed to be mediated by antibodies directed against leukocyte antigens (human leukocyte antigen, HLA, or human neutrophil antigen, HNA). Depletion of leukocytes to less than 5×10^6 has been shown to prevent, or at least ameliorate, such reactions in most patients. Increasing evidence suggests that cytokines play a role in causing these reactions. Because cytokines may be released from leukocytes during storage, pre-storage leukoreduction is preferred.

A second important indication for LRRCs is the mitigation of alloimmunization to HLA antigens that can adversely affect post-transfusion platelet increments and the search for HLA-compatible donors for stem cell and solid organ transplantations. This approach will be effective only if leukoreduced platelets are also used. According to current AABB standards, the total leukocyte number must be less than 5×10^6 when intended for this purpose, an achievable goal with third-generation leukoreduction filters. A multicenter study known as TRAP (Trial to Reduce Alloimmunization to Platelets) showed that the use of leukoreduction filters for platelet products significantly decreased the rate of alloimmunization but did not completely eliminate the problem.

A third indication for the use of LRRCs is to prevent transfusion-transmitted cytomegalovirus (CMV). CMV is found in low copy numbers outside of cells, and leukoreduced blood components are considered CMV safe. RBCs that are either leukoreduced or from CMV-seronegative donors are associated with only 1% to 1.5% CMV-transmission rates; thus, many institutions provide leukoreduced RBCs to mitigate CMV transmission.

A final indication for the use of LRRCs is to prevent transfusion-related immunomodulation (TRIM). A large meta-analysis previously demonstrated that patients who receive a blood transfusion are more likely to experience a postoperative infection than patients not transfused. This effect has been found to be dose-dependent and is thought to be mediated by suppressing the patient's immune function. In addition, some studies have suggested that TRIM may be associated with cancer recurrence, but other studies have refuted this notion. The mechanism of TRIM has yet to be defined, but multiple theories have been proposed. It has been suggested that immunologically active WBCs or soluble biologic response modifiers released from WBCs during storage downregulate the recipient's immune function. Alternative theories suggest that soluble mediators circulating in allogeneic plasma may have an immune-modulatory effect. Universal leukoreduction has been found by some studies, but not by others, to mitigate the immunomodulatory effect of allogeneic transfusions.

Washed Red Blood Cells

RBCs are washed using isotonic saline solutions mainly by automated techniques. There is always some degree of RBC loss with each wash cycle. Because most automated methods utilize open systems, the resulting product must be transfused within 24 hours to prevent bacterial growth.

The primary aim of washing is to remove plasma proteins, although some leukocytes and platelets are removed simultaneously. The major indication for washed RBCs is the prevention of severe allergic transfusion reactions, most likely mediated by recipient IgE antibodies against donor plasma proteins. Washing is recommended when reactions are severe and refractory to pre-transfusion steroid and antihistamine administration. In IgA-deficient patients who have preformed antibodies to IgA, the exposure to IgA-containing plasma can cause anaphylaxis. Therefore, high volume cell washes may be required to prepare cellular components for transfusion in IgA-deficient patients.

Irradiated Red Blood Cells

RBCs are irradiated with either gamma-ray or X-ray technology with a minimum dose of 25 Gy not exceeding 50 Gy. RBCs expire 28 days after irradiation or on the original expiration date, whichever is sooner. A method is used to ensure that irradiation has occurred with each batch. The primary aim of irradiation is to prevent the rare, but often fatal risk of transfusion-associated graft-versus-host disease (TA-GVHD) by the abrogation of the proliferative potential of donor T lymphocytes. GVHD can occur after the transfusion of immunologically competent donor lymphocytes, usually to an immuno-incompetent recipient. Some patient populations with indications for irradiated products include neonates, patients with hematologic malignancies, stem cell transplant recipients, and patients with congenital immune deficiencies. There is still much debate among experts regarding which additional patient populations may be at risk for TA-GVHD. It has been suggested that a policy of universal blood component irradiation could prevent TA-GVHD in patients with currently unsuspected risks, including advanced age, unrecognized immune deficiencies, or unsuspected donor-recipient immune similarities. If efficacious systems to apply pathogen reduction to red cell components by induction of DNA/RNA cross-linking become approved, another advantage would be the inactivation of white cells, which would eliminate the need for gamma irradiation to prevent TA-GVHD.

Frozen Red Blood Cells

RBCs can be frozen (with glycerol used as a cryoprotective agent) and stored at −65°C or colder. The required concentration of glycerol depends on the rate and the temperature of freezing. The freezing process destroys other blood constituents, except for a small percentage of immunocompetent lymphocytes. RBCs are prepared for transfusion by thawing and washing away the glycerol using a series of progressively less hypertonic crystalloid solutions, allowing glycerol to diffuse gradually from the cells to prevent hemolysis. The cells are resuspended in an isotonic saline solution containing glucose. The extensive washing removes approximately 99.9% of the plasma as well as cellular debris.

RBCs can be stored in the frozen state for at least 10 years with good viability. After thawing and washing, storage is typically limited to 24 hours because of the open system. Frozen cells have been shown to maintain prefreezing adenosine triphosphate (ATP) and 2,3-diphosphoglycerate (DPG; also known as 2,3-bisphosphoglycerate or 2,3-BPG) levels. To maintain these factors at high levels, the standard is to freeze within 6 days of collection. When it is necessary to freeze older units, rejuvenation with a solution containing pyruvate, glucose, phosphate, and adenine has provided excellent results. The major indication for frozen RBCs is the stockpiling of rare donor units for patients who have developed alloantibodies. Some patients with rare phenotypes can make autologous donations that can be frozen for later use. Cells from autologous donors can be frozen if more units are required than can be collected in the 42-day liquid storage period or if surgery is postponed. Because of the high cost, lower product quality, and cumbersome nature of freeze-thaw procedures, other uses of frozen RBCs are somewhat difficult to justify.

APPROPRIATE TRANSFUSION PRACTICE IN VARIOUS CLINICAL SETTINGS

The response to RBC transfusion varies from patient to patient. In the absence of increased red cell destruction or sequestration, one unit of RBCs can be expected to increase the Hb level by 1 g/dL or the hematocrit level by approximately 3%. This rise is usually not fully realized until approximately 24 hours after transfusion, when the plasma volume has had time to return to normal. On the basis of a half-life of approximately 57.7 days for donor red cells, Mollison and associates calculated that an average-sized adult requires 24 mL of RBCs per day to maintain a given hematocrit level, assuming no red cell production. Patients with red cell aplasia require approximately 2 units of RBCs every 2 weeks.

Several factors can adversely affect the survival of transfused red cells. Hemolysis, caused by either immune-mediated red cell damage or mechanical trauma, shortens the survival of transfused cells, much as it shortens the survival of the patient's own cells. Hypersplenism can lead to initial sequestration as well as increased destruction of red cells. Continued blood loss is another obvious cause of suboptimal response to transfusion. It should also be emphasized that transfusion suppresses erythropoiesis, so that the net result of transfusion may be less than expected if transfusions are administered on a chronic basis.

Chronic Anemia

As a rule, signs and symptoms attributable to anemia are unlikely to develop at a Hb level of greater than 7 g/dL. When the anemia is of gradual onset, the body's compensatory mechanisms for maintaining oxygen delivery to the tissues come into play. Both cardiac output and intracellular 2,3-DPG increase, and thus, oxygen unloads at a lower oxygen saturation of Hb. When chronic anemia is due to red cell destruction, the healthy bone marrow responds by increasing erythropoiesis up to sixfold.

RBC transfusion provides symptomatic support rather than definitive therapy for anemia. Transfusion should be used only when there is no definitive treatment for the underlying cause (i.e., iron, vitamin B12, or folate supplementation) or when the severity of the anemia and the clinical manifestations in the patient make it impossible to wait for the effects of treatment to be realized.

Generalizations about RBC transfusion indications and practices are difficult to make and are usually inappropriate. The clinical impact of anemia varies depending on its pathogenesis, rate of onset, the presence or absence of accompanying hypovolemia, and, most importantly, the individual patient. The Hb level at which a given individual manifests the signs and symptoms of anemia relates, in part, to underlying health status, cardiorespiratory reserve, and tissue oxygen demand. Studies have shown that the risk of death increases with the severity of chronic anemia; it is prudent to maintain the Hb level above four for otherwise healthy patients and six for patients with cardiac disease to avoid sudden cardiac arrhythmias that are often fatal.

Perioperative Period

Many generalizations have been made about the appropriate transfusion management of acute blood loss, often with little evidence to support the arguments. One rule of thumb is that blood loss of 10% or less of total blood volume requires no replacement therapy at all; loss of up to 20% can be replaced exclusively with crystalloid solutions; and loss of greater than 25% generally requires RBC transfusion to restore oxygen-carrying capacity, along with crystalloid and sometimes colloid solutions to restore intravascular oncotic pressure to achieve adequate perfusion. A RBC transfusion trigger of 7 g/dL of Hb is now commonly used during the perioperative period. Each case must be evaluated individually on the basis of clinical signs and symptoms, rather than laboratory values alone. If the cardiovascular system is healthy and the degree of hypoperfusion is not significant, good tissue oxygenation can be maintained at much lower Hb levels. Many anesthesiology and surgery clinical guidelines suggest that most surgical patients do not need transfusion unless the Hb level falls to less than 7 g/dL. Given that RBC transfusion should be tailored to individual needs, the question arises as to whether there is any readily available, objective measurement that can be used to determine how low the Hb level can safely be allowed to fall before RBC transfusion is initiated.

Global hemodynamic parameters do not always correlate with microvascular perfusion. Assessment of tissue oxygenation at the microvascular level would help evaluate the effectiveness of a red cell transfusion, evaluate the effect of red cell storage on end-organ perfusion, and provide data about when to transfuse. Several general methods are available to evaluate the microcirculation and include direct assessment using image techniques and indirect methods of assessment, such as measures of microvascular oxygen availability and function. Direct assessment can be performed using laser Doppler flowmetry, imaging of the microcirculation, intravital microscopy, orthogonal polarization spectral imaging, and sidestream dark-field imaging. Assessments of oxygen availability include oxygen electrodes, reflectance spectrophotometry, and near-infrared spectroscopy. The techniques described are currently considered research tools and are not available in routine clinical practice. None has yet to prove reliable and reproducible in the clinical setting. Further, some are only useful in specific organ systems and do not reflect the global oxygenation of the patient. To be useful at the bedside, a technique must be technically simple, rapid, and noninvasive without large interoperator variation. Such a device has yet to become available.

In 2019, the Society of Cardiovascular Anesthesiologists published clinical practice guidelines focusing on blood conservation interventions, such as erythropoietin or antifibrinolytic administration, intraoperative blood salvage, or normovolemic hemodilution, and provided practical intraoperative transfusion algorithms guided by point-of-care viscoelastic methods and standard coagulation laboratory values.

Randomized clinical trials have evaluated the effects of different transfusion thresholds in distinct clinical settings; however, the thresholds used in the studies differ widely. Many of the studies found no difference in outcome. Most studies were not powered to adequately evaluate clinically important outcomes. Few studies included more than 100 patients. The TRICC trial included 838 intensive care unit (ICU) patients who were randomized to a restrictive transfusion strategy (transfused at Hb 7 g/dL) or liberal strategy (transfused at 10 g/dL). The 30-day mortality was slightly lower in the restrictive group (18.7% vs. 23.3%), but not significantly lower. The FOCUS trial, a 2600 patient, multicenter randomized trial designed to determine whether patients with cardiovascular disease or risk factors undergoing surgical repair of the hip benefit from a lower (<8 g/dL) or liberal transfusion trigger (transfused at 10 g/dL) showed that liberal transfusion did not reduce mortality or in-hospital morbidity in this patient cohort. Other studies have now been published in sepsis (TRISS), upper gastrointestinal (GI) bleeding (Villanueva et al.), pediatric intensive care (TRIPICU), and cardiac surgery (TRACS, TITRe2) that support the use of conservative transfusion triggers.

Red Blood Cell Transfusion in Neonates

In neonates, it is convenient to consider periodic, small-volume transfusion separately from massive transfusion situations. The trigger for transfusion and the optimal type of component are very different in these two settings. The potential adverse effects may be quite distinct.

Low-volume RBC transfusion is rarely indicated in full-term infants unless acute blood loss has occurred at birth or an intrauterine situation has led to prenatal anemia. In contrast, premature infants are frequent recipients of transfusions. In the intensive care setting, the premature infant is subjected to frequent blood sampling, and iatrogenic anemia may necessitate transfusion. Anemia of prematurity is also a well-recognized entity; premature infants have a slightly lower Hb value at birth. In addition, the postnatal decline in Hb occurs earlier and is more pronounced in premature infants. The mechanism for anemia of prematurity appears to involve a relatively lower output of erythropoietin in response to a given degree of anemia. This phenomenon is attributed in part to the fact that the liver, rather than the kidney, is the major site of erythropoietin production in these infants. Although some practitioners have considered this degree of anemia to be physiologic, the benign nature of this condition remains controversial.

Another debate among neonatologists concerns the triggers for RBC transfusion, as in what clinical signs and symptoms are valid reflections of poor tissue oxygenation. Congestive heart failure and severe pulmonary disease are generally accepted indications for transfusion, but recurrent apnea, tachypnea, tachycardia, and failure to thrive are also used as transfusion triggers. In recent times, the rate of transfusion and the donor exposure rate of premature infants have consistently declined. These changes, however, reflect improvements in patient care (e.g., microtesting methods resulting in less iatrogenic blood loss; the use of surfactant resulting in decreased respiratory distress and the use of a single unit to supply one infant over a longer period) rather than being attributable to changes in the transfusion trigger. The prolonged use of single units has become possible with the advent of the sterile docking technology that preserves the full shelf-life of the unit of RBCs, as well as with the accumulating evidence that fresh blood is not necessary for low-volume transfusions in neonates because supernatant potassium and decreased pH are not of concern in this setting. Recent studies have provided additional information about the relative risks and benefits of using restrictive rather than more liberal criteria for very low birth weight infants. Two studies showed that a liberal transfusion practice resulted in more infants receiving transfusion but conferred little evidence of clinical benefit. One study showed a lower risk of apnea and major brain injury for the liberal transfusion arm of the study. Therefore, the safest transfusion trigger in the preterm infant still remains unclear, and further studies are indicated. Most institutions assess the clinical situation and consider the postnatal age and whether a neonate has oxygen requirements when determining the need for a RBC transfusion.

The dose of a RBC transfusion in a neonate can vary by institution between 10 and 20 mL/kg. Few studies have assessed the optimal dose in this patient population, and further studies are needed. Paul et al. compared 10 and 20 mL/kg and found that the larger volume did not cause impaired pulmonary function. Wong et al. demonstrated extra transfusion episodes could be avoided with 20 mL/kg versus 15 mL/kg, without any additional risk to the patient. Many transfusion services now routinely use RBCs stored in additive solutions for low-volume RBC transfusion and thus prefer a dose of 20 mL/kg to account for the lower hematocrit of an additive unit.

Finally, several trials of erythropoietin therapy in premature infants have been undertaken. The administration of relatively high-dose erythropoietin has been shown to raise Hb levels and reticulocyte counts in healthy premature infants, but the effect in sicker neonates is unclear. Although transfusion exposure was decreased, the significance of this observation is diminished, given the promise of new strategies for limiting transfusions and donor exposure. The high cost and the increased risk of retinopathy associated with erythropoietin treatment does not justify its use in this patient population.

In the case of massive transfusion, the situation differs. There have been marked increases in massive transfusion in recent years in full-term as well as premature infants. Hemolytic disease of the newborn remains a prominent indication for exchange transfusion; however, the recent use of intravenous immune globulin to decrease red cell antibody levels in newborns has decreased the necessity of this procedure. The two triggers for exchange are (a) rapidly rising levels of unconjugated bilirubin that may lead to kernicterus and permanent central nervous system damage and (b) congestive heart failure secondary to severe anemia. Whole blood exchange transfusion is especially beneficial in cases of hemolytic disease of the newborn because it clears the bilirubin, the offending antibody, and the antibody-coated red cells before lysis while providing a source of red cells lacking the offending antigen. A two-blood-volume exchange is commonly performed by using a fresh unit of blood concentrated to a final hematocrit level of approximately 50%. In cases of hyperbilirubinemia resulting from other causes (e.g., liver immaturity in premature infants), phototherapy is the treatment of choice because its effects are usually more sustained, and exchange transfusion is used only for cases of marked elevations. Extracorporeal membrane oxygenation and open-heart surgery are two other situations when the neonate may be exposed to large volumes of allogeneic RBCs. The extracorporeal membrane oxygenation circuit requires a prime with RBCs, as do many of the types of extracorporeal circuits used for cardiopulmonary bypass.

Although accumulating evidence supports the safety of using RBC units of any age and with any preservative solution for low-volume transfusions in neonates, the same transfusion policies may not apply to massive transfusion. Newborn physiology is unique in several ways that may have implications for massive transfusion therapy. The newborn does not handle metabolites in a mature fashion. Renal immaturity may lead to problems in clearing potassium or acid from stored RBCs, and the immature liver may not catabolize citrate efficiently. These problems are accentuated and protracted in the premature infant. To address the concern about potassium load, fresh (<7 days old) or washed RBCs are often used, although the necessity of this practice is actively debated. Fresh blood may also be preferred because of its higher 2,3-DPG levels and better red cell integrity. The citrate problem is probably best handled by using slow infusion rates because the use of bicarbonate or calcium replacement to counteract the acid load or calcium-chelating effects of citrate is controversial. AS-3 may be preferentially chosen over AS-1 because of the theoretical concern over mannitol content that is absent in AS-3 but present in AS-1. However, in the context of multiple, small-volume transfusions, either AS is considered safe.

The humoral and cellular immune systems of the neonate are immature, especially in the premature infant. There is a small but real risk of transfusion-induced GVHD in premature infants receiving RBC transfusions and in the fetus undergoing intrauterine transfusion. Irradiation of RBCs should be performed in both settings. Another risk of transfusion in low birth weight (<1500 g) premature infants is the development of clinical CMV infection in infants of CMV-seronegative mothers. CMV-safe blood, either CMV seronegative or leukoreduced, should be provided to these infants. Some retrospective observational studies have suggested that other rare RBC transfusion-associated complications in this particularly vulnerable patient group may include necrotizing enterocolitis, intraventricular hemorrhage, bronchopulmonary dysplasia, and retinopathy of prematurity. However, a causal relationship has yet to be established through clinical studies. In multivariable analyses, some studies have suggested that severe anemia, and not transfusion itself, may be associated with these outcomes.

Ideas to prevent anemia and decrease donor exposure in premature infants and other neonates include delayed cord clamping, cord milking, umbilical vein blood sampling from the delivered placenta, and autologous cord blood transfusion. One review of 10 delayed cord clamping studies demonstrated lower transfusion requirements in the delayed versus early clamped group. However, a randomized controlled trial by Strauss et al. found no difference in transfusion needs between delayed and early clamped groups. A few studies have looked at autologous cord blood transfusions in neonates. One study found that the amount of blood harvested was insufficient to cover all transfusions in low-birth-weight infants. In addition, studies have demonstrated that blood processing problems, bacterial contamination, and costs are all barriers to the routine collection and autotransfusion of cord blood.

Red Blood Cell Transfusion in the Allogeneic Hematopoietic Stem Cell Transplantation Recipient

Red cell engraftment is usually the last phase of hematopoietic recovery after stem cell transplantation; therefore, RBC transfusion is common during the posttransplantation period. As hematopoietic stem cells and progenitor cells lack ABO antigens, the transplantation outcome is not significantly affected by the red cell antigen/antibody incompatibility between the donor and the recipient. However, RBC transfusion requirements and blood product selection can vary significantly depending on the type of ABO incompatibility. The phenotyping of non-ABO/Rh red cell antigens from the donor and recipient is not required in the absence of a positive red cell antibody screen in the recipient. Patients with an autologous stem cell transplant have fewer RBC transfusion requirements when compared with patients receiving allogeneic stem cell transplantation.

In the setting of allogeneic stem cell transplantation, there are four major categories of ABO antigen matching: full compatibility, minor incompatibility, major incompatibility, and bidirectional incompatibility. In addition, Rh type must be taken into consideration. Rh-positive recipients with Rh-negative donors should receive Rh-negative RBCs, but Rh-negative recipients with Rh-positive donors may receive Rh-positive RBCs. Apheresis platelets and plasma may be given without regard to Rh. The blood product selection algorithm is shown in (Table 112.2). Minor incompatibility is defined as the presence of blood group antibodies in donor plasma (e.g., group O donor to group A recipient). In minor incompatible stem cell transplantation, the incompatible plasma in the donor stem cell product may result in some hemolysis of the recipient's endogenous RBCs during the early phase of the posttransplantation period. Minor incompatibility is occasionally complicated by passenger lymphocyte syndrome, where transient hemolysis may occur if donor-derived lymphocytes in the stem cell graft remain viable and form blood group–specific antibodies that are incompatible with the recipient's red cells. Typically, passenger lymphocyte syndrome involves ABO incompatibility, but hemolysis resulting from serologic incompatibility in other blood group systems has been reported. If hemolysis increases a few days after transplantation, passenger lymphocyte syndrome should be considered. Once the donor is engrafted and incompatible recipient red cells are removed, donor red cells will have normal survival in the recipient. Major incompatibility is defined by the presence of blood group antibodies in recipient plasma (e.g., group A donor to a group O recipient). Major ABO-incompatible transplantation may result in pure red cell aplasia (PRCA) due to persisting incompatible ABO antibodies targeting the donor's engrafting erythropoietic precursors expressing ABO antigens. Although there may be no evident hemolysis, the donor red cell engraftment could be further delayed and result in prolonged RBC transfusion support. Finally, bidirectional incompatibility is defined as the presence of incompatible ABO antigens and antibodies contributed by both donor and recipient (e.g., group A donor to group B recipient). Bidirectional incompatible transplants may cause the problems associated with both minor and major ABO-incompatible transplants. To predict the severity of these complications and provide management, an ABO antibody titer can be performed on either the stem cell product or the recipient. However, titers do not correlate perfectly with the clinical outcomes. When a high titer incompatible ABO antibody is discovered in a minor incompatibility, the stem cell product can be plasma-reduced to avoid an immediate hemolytic reaction. Occasionally, in major incompatibilities, plasma exchange can be considered if the recipient has a high level of incompatible ABO antibodies to prevent hemolysis at the time of transplant or PRCA.

TABLE 112.2 Transfusion After ABO-Incompatible Hematopoietic Stem Cell Transplantation

ABO Group			Product Selection	
Donor	Recipient	Type of Mismatch	RBC	Plasma/ Platelets
A	O	Major	O	A
A	B	Bidirectional	O	AB
A	AB	Minor	A	AB
B	O	Major	O	B
B	A	Bidirectional	O	AB
B	AB	Minor	B	AB
O	A	Minor	O	A
O	B	Minor	O	B
O	AB	Minor	O	AB
AB	A	Major	A	AB
AB	B	Major	B	AB
AB	O	Major	O	AB

RBC, Red blood cell.

RED BLOOD CELL PRESERVATION AND STORAGE

The first key to the storage of blood is a stable, minimally toxic anticoagulant with preservative properties. During the early 1900s, it was recognized that citrate met these criteria. Citrate is slightly more toxic than heparin, especially when given rapidly and in large amounts, but citrate has preservative action that heparin lacks. Citrate has the added advantage of not causing systemic anticoagulation in the recipient.

The other factor essential for long-term storage is a mechanism to maintain cell viability and function. Freshly transfused RBCs have a good survival rate in the recipient's circulation, with a destruction rate approximately equal to that of the recipient's own cells: 1% per day.

However, changes within the RBC and its supernatant during RBC storage have been associated with reduced tissue oxygenation and other adverse effects in patients receiving RBC components stored for extended periods. The biochemical, structural, and functional changes are collectively termed the red cell storage lesion. RBC donor characteristics such as social behaviors and inherited genetic variants as well as RBC component processing techniques may also affect the storage lesion. The alterations found with the storage lesion along with the clinical implications are discussed in this section.

BIOCHEMICAL CHANGES ASSOCIATED WITH RED BLOOD CELL STORAGE

Adenosine Triphosphate Levels

ATP levels appear to be a major determinant of red cell viability. The drop in cellular ATP levels during storage has been correlated with increased cell rigidity and with loss of membrane lipid, leading to decreased red cell life span. For this reason, most efforts to extend RBC storage have focused on ways to maintain intracellular ATP levels. First, dextrose was introduced into the citrate solution (citrate-phosphate-dextrose [CPD]: 21-day shelf-life), and then adenine was added (CPDA-1: 35-day shelf-life). Three additive solutions containing additional dextrose and adenine (Nutricel, or AS-3) or dextrose and adenine plus mannitol (Adsol, or AS-1) and (Optisol, or AS-5) allow extension of the maximum storage time to 42 days (Table 112.3). Most of today's RBC supply is stored in an additive solution.

TABLE 112.3 **Biochemical Changes in Stored Red Blood Cells**

Variable	CPDA-1	CPDA-1	Adsol
In vivo survival (at 24 h) (%)	100	<71.0	<88.0
pH	<7.5	<6.7	<6.7
ATP (% initial)	100	<45.0	<76.0
2,3-DPG (% initial)	100	<10.0	<10.0
Plasma K^+ (mEq/L)	5.1	<78.5	<49.0

ATP, adenosine triphosphate; *CPDA*-1, citrate phosphate dextrose adenine-1; *DPG*, diphosphoglycerate.
Data from Zuck TF, Bensinger TA, Peck CC, et al. The in vivo survival of red blood cells stored in modified CPD with adenine: report of a multi-institutional cooperative effort. *Transfusion*. 1977;17:34; and Moore GL, Peck CC, Sohmer PR, et al. Some properties of blood stored in anticoagulant CPDA-1 solution. a brief summary. *Transfusion*. 1981;21:135.

2,3-Diphosphoglycerate Levels

Stored RBCs must also maintain their capacity to deliver oxygen. It was not until 1967 that the central role of 2,3-DPG in releasing oxygen from oxyhemoglobin was recognized. Attention was then focused on ways to maintain high levels of 2,3-DPG in stored RBCs. The first anticoagulant introduced on a large scale, acid citrate-dextrose, was ineffective because of its low initial pH; however, the subsequently developed CPD, with its higher initial pH and slower fall in pH, was superior. CPDA-1 and additive solutions have not further improved 2,3-DPG maintenance. Although 2,3-DPG depletion of stored RBCs is known to decrease oxygen delivery, the clinical significance of this finding is unclear. 2,3-DPG levels in stored RBCs are rapidly regenerated in vivo, rising to greater than 50% of normal within several hours and to normal within 24 hours of transfusion. Although a patient with normal cardiac status should be able to compensate by increasing cardiac output to maintain normal oxygen delivery until 2,3-DPG levels are regenerated, an improvement in 2,3-DPG preservation in stored RBCs is still desirable.

Citrate

Infusion of large volumes of blood with citrate anticoagulant over a short period may cause plasma citrate levels to reach the toxic range. The primary concern is the cardiovascular effects of hypocalcemia caused by the chelation of calcium by citrate. The risk of citrate toxicity is exacerbated by liver dysfunction or liver immaturity. Despite these theoretical considerations, there is little documented evidence of clinical citrate toxicity, which can usually be prevented by slower infusion. If large amounts of blood have to be infused over a very short period, administration of calcium gluconate can be considered, but whether the benefits justify the risk is controversial.

Potassium

Another issue with prolonged storage is the excess potassium in the RBC supernatant that could potentially cause cardiac arrhythmias. At a storage temperature of 4°C, the red cell sodium-potassium pump is essentially nonfunctional, and intracellular and extracellular levels gradually equilibrate. In addition, hemolysis results in increased potassium in the supernatant. However, because the total volume of plasma in RBC concentrates is low (approximately 70 mL), the total potassium burden is only approximately 5.5 mEq at product expiration. Practically speaking, the potassium load is rarely a clinical problem except in the setting of preexisting hyperkalemia and renal failure in adults or in some recipients of massive amounts of irradiated red cells In children with rapid or massive transfusions, hyperkalemic cardiac arrest is more commonly recognized. In these situations, fresher units of RBCs or washed RBCs can be used.

Di(2-ethylhexyl)phthalate

Since their introduction in the 1960s, plastic blood bags used for storing RBCs have been made from polyvinylchloride containing the lipophilic plasticizer di(2-ethylhexyl)phthalate (DEHP), which confers pliability. The safety of DEHP has been questioned for years owing to its tendency to leach from the bag and to be present at levels of 50 to 70 mg/L in stored RBCs. The storage of RBCs in bags made of polyvinyl chloride plasticized with DEHP has caused more recent concern because of the reported association between DEHP exposure and impaired development of the male genital tract. Due to these concerns, there has been increased discussion in Europe surrounding eliminating DEHP from blood bags. One of the benefits of using DEHP for RBC storage is the prevention of hemolysis. DEHP leaches out from the plastic bag and intercalates and stabilizes the red cell membrane. Shorter storage lessens the load of DEHP delivered to the recipient. Although there are potential replacement plasticizers, DEHP is most commonly used since the exposure to DEHP through transfusion is generally felt to be less than other environmental exposures.

Storage Length of Red Blood Cells

Current Status

The current expiration time of an RBC unit stored in an additive solution is 42 days. The allowable storage time is regulated by the FDA and requires: (1) the recovery of at least 75% of red cells transfused 24 hours after infusion, and (2) less than 1% hemolysis, both at the end of the storage limit. There is no criterion based on the clinical ability of transfused red cells to oxygenate tissue. The 2017 National Blood Collection and Utilization Survey reported that 18% of RBCs are transfused during their last week of life, between days 35 to 42.

Many variables affect the age of a specific RBC unit at transfusion. The blood group of the unit will impact the length of storage. Group O units tend to be issued quickly due to their universal compatibility; as a result, Group O units are often issued with a shorter age. Group B and AB tend to be stored the longest. Transfusion service policies will also affect the overall age of RBC units at the time of transfusion. Busy tertiary care hospitals tend to transfuse some of the oldest units since they may receive units returned from smaller community centers that did not expect to use them before their outdate. Hospitals that have blood refrigerators outside the blood bank tend to age units in the refrigerators because it is cumbersome to rotate the units out frequently. Hospitals with high crossmatched to transfused ratios also tend to have older units on their shelves.

Red Blood Cell Storage Lesion

The RBC storage lesion includes all the changes that occur to blood components during blood bank storage. The lesion includes biochemical and structural changes to the red cell, as well as changes that occur in the storage supernatant. The structural changes include red cell membrane loss that leads to the reversible evolution of the shape of the red cell from a biconcave disc to a spheroechinocyte. After this stage, further red cell membrane loss becomes irreversible, and microvesicles are produced. Red cell vesicles are quickly cleared by macrophages due to exposed negatively charged lipids. The infusion of a large amount of red cell vesicles during a RBC transfusion may overwhelm the reticuloendothelial system and cause a proinflammatory and prothrombotic response. The shape changes are also associated with a rheologic effect, including increased viscosity and reduced flow within the capillaries, leading to decreased tissue perfusion. Many of the biochemical and structural changes, aside from vesiculation, are reversible when the RBCs enter human circulation where pH, ATP levels, and 2,3-DPG levels are normal.

Older red cells become more susceptible to oxidative damage, although this change generally occurs at a lower rate during in vitro conditions than in vivo due to the lower storage temperature. However, during a transfusion, the human circulation is confronted by a bolus of equally damaged RBCs that may overwhelm the reticuloendothelial system. The work of Hod and Spitalnik emphasized that up to 25% of transfused RBCs with prolonged storage are cleared within 24 hours. The rate of delivery of heme-iron to the reticuloendothelial system may abruptly increase as much as 60-fold after transfusion of even a single unit of RBCs. This can surpass the rate of uptake by transferrin and produce circulating nontransferrinbound iron that may in turn lead to the myriad of problems associated with iron overload.

Irradiated cells are exposed to additional oxidative stress that can damage red cell protein and lipid. WBCs in the component also break down during storage and release proteases and lipases. Lysophospholipids and glycosidases are produced. Glycosidases may remove sialic acid and other sugars from the red cell membrane and can cause increased binding of stored red cells to endothelial cells and potentially contribute to endothelial inflammation. Increased lysophospholipids, such as platelet activating factor, have been found in units that have caused TRALI.

Certain blood donor characteristics may also enhance the red cell storage lesion. For example, glucose-6-phosphate dehydrogenase (G6PD) deficiency decreases the ability of RBCs to withstand oxidative stress, and RBCs from G6PD-deficient donors have been associated with reduced 24-hour post-transfusion recovery (mean 78.5% vs. 85.3%, $P = .0009$). In addition, blood donor smoking has been associated with increased RBC osmotic fragility and oxidative stress. RBCs donated by smokers that undergo irradiation have been associated with reduced post-transfusion Hb increments compared to RBCs irradiated from non-smokers (mean 0.74 g/dL vs. 0.94 g/dL, $P = .045$), suggesting a potential two-hit mechanism on RBC quality.

Clinical Relevance of the Red Cell Storage Lesion

Retrospective or prospective observational studies in many diverse patient populations have suggested numerous adverse events that may be associated with prolonged RBC storage, including increased risk for mortality, postoperative infection, multiorgan failure, deep venous thrombosis, or increased length of stay in the ICU or hospital. The observational studies on this topic have a number of significant limitations. First, larger volumes of RBC transfusion predict worse outcomes. Patients who are transfused larger volumes are statistically more likely to receive older RBCs. Second, confounding factors may not be recognized and, as a result, are discounted in nonrandomized studies. Third, individual methodologies in the presently available studies have varied markedly. Some studies have looked at the effect of mean storage age of all units transfused on outcome, and some have broken storage time into categorical groups (i.e., is storage less than 14 days safer than storage beyond 14 days). In addition, studies have not used a single definition for “older” units; some have defined older units as greater than 14 days, greater than 21 days, or greater than 28 days. The definitions of age have not been based on either clinical or microcirculatory relevance or related to the feasibility and practicality of blood collection. Most studies have been designed for convenience and feasibility; a red cell storage age study with a definition of an older RBC unit as greater than 14 days of storage is achievable given current hospital inventories. Fourteen days is close to the average age of RBCs stored in a blood bank, but from a blood collection and inventory management perspective, an expiration time of 14 days would be disastrous for both hospitals and blood collection facilities. Authorities have argued that studies should be designed to measure storage age differences between lengths of storage that would actually be achievable given current inventory levels and difficulties in donor recruiting.

Published studies have focused on three patient groups that consume large numbers of RBC components: cardiac surgery, trauma, and critical care patients. A publication on the effect of RBC storage age on hematopoietic transplant recipients has also been recently published.

The Age of RBCs in Premature Infants study, a double-blinded study evaluating the effectiveness of RBCs stored no longer than 7 days versus standard-issue RBCs in 377 neonates requiring transfusions has been published. The primary outcome revealed that using fresh blood of less than 7 days-old did not improve the clinical outcome of these vulnerable premature infants. The Age of Blood in Children in Pediatric ICUs trial (ABC PICU) examined the effect of transfusing less than 7-day old blood (versus standard-issue age) in 1538 pediatric ICU patients (age range 3 days to 16 years, median age 1.8 years). The randomized study found that fresh versus standard-issue red cells did not decrease new or progressive multiple organ dysfunction syndrome or ICU mortality. The two groups also had similar rates of sepsis and acute respiratory distress syndrome.

The Red Cell Storage Duration Study evaluated 1098 patients undergoing complex cardiac surgical procedures who were likely to require RBC transfusion. Patients were randomized to receive RBC units stored for either 10 or fewer days or 21 or more days. The median storage times of the transfused RBCs were 7 days versus 28 days for the two groups. RBC storage duration was not associated with a change in the Multiple Organ Dysfunction Score (MODS) or the 28-day mortality. Adverse events did not differ between the groups, except that hyperbilirubinemia was more common in the older storage age group.

The Age of Blood Evaluation study investigated the effect of leukoreduced RBCs stored 7 days or less versus leukoreduced standard-issue RBCs on 90-day all-cause mortality. Investigators enrolled 2430 adult participants receiving their first RBC unit in an ICU. The study found that fresh versus standard-issue RBCs did not decrease 90-day mortality among critically ill adults.

The current RBC inventory almost always meets hospital needs with a 42-day RBC expiration period but is not currently equipped to meet the needs of a less than 7-day inventory, or even a less than 21-day inventory. Although it is logical to expect that there is a limit to RBC storage, beyond which the risks of transfusion outweigh the benefits of transfusion, none of the randomized studies described above is designed to determine this limit. In a study of autologously transfused RBCs, those transfused at later times (days 40 to 42 of storage) were associated with increased post-transfusion bilirubin and non-transferrin-bound iron, as well as increase in transferrin saturation, compared to transfusion of fresh units (days 3 to 7 days of storage). This finding suggests that units transfused in the last week of storage (days 35 to 42) may demonstrate decreased quality, and raises potential safety concerns and implications for blood bank inventory management.

RED CELL ALLOIMMUNIZATION

Overview

RBCs have over 300 blood group antigens that are capable of mounting humoral responses in antigen-naïve transfused recipients. Direct exposure to nonself red cells from allogeneic blood transfusion, circulating fetal red cells in pregnant females, or even occasionally stem cell/organ transplantation can cause red cell alloimmunization. In addition, recent studies have shown that indirect immune modulation mediated via proinflammatory factors in stored RBCs, a proinflammatory state in the host (e.g., endothelial damage or higher turnover rate of red cells in patients with chronic transfusion), and passive transfer of WBC antibodies (anti-HLA and anti-HNA) are associated with a higher risk of RBC alloimmunization. Matzinger’s

Danger Theory/Model further proposes that nonself antigen exposure with local danger signals from injured cells can synergize immune responses. Therefore, red cell alloimmunization represents a complex interplay between transfused allogeneic RBCs and host immunity.

The humoral response can be categorized into two phases. The primary response occurs immediately when foreign antigen activates B lymphocytes leading to the high-affinity mutation-selection process. This process allows the activated B cells to proliferate and differentiate into memory/plasma B cells that produce a specific antibody against the antigen, although the initially generated antibody may not lead to significant hemolysis of sensitized red cells. Upon re-exposure to the same antigen (e.g., transfusing an individual who had preformed antibody but at an undetectable level), the second phase of the immune response (anamnestic response) can lead to rapid and robust antibody production from the pre-generated antigen-specific memory/plasma B cells. This response often causes clinically significant hemolysis that may even lead to a fatality in these transfused individuals. There are two isotypes of red cell antibodies that are routinely evaluated in the blood bank. Immunoglobulin M (IgM) is a pentavalent antibody that appears during the early phase of antibody generation. It is primarily restricted to the intravascular compartment, can fix complement on the transfused red cells with cognate antigens, and could result in intravascular hemolysis. On the contrary, IgG antibody is produced mostly by memory/plasma B cells that can migrate to the extravascular compartment (e.g., amniotic fluid and tissues). Due to its capacity to move between compartments, IgG antibodies are commonly associated with extravascular hemolysis and fetal hemolysis.

Individuals at Risk

Both the immunogenicity and quantity of foreign red cell antigens are critical determinants of alloimmunization. Therefore, frequent transfusion exposure and transfusion across different ethnic groups are the most common factors associated with alloimmunization. This issue is of great concern in patients with transfusion-dependent hemoglobinopathies (e.g., sickle cell disease [SCD] and thalassemia) and PRCA (e.g., Diamond-Blackfan anemia). In particular, SCD is associated with rapid sequestration of defective red cells and endothelial damage. The racial discrepancy in the prevalence of certain red cell antigens, such as in the Rh system (DCcEe) and Kell (K1), between blood donors (mostly European descent) and SCD patients (mostly African descent) significantly contributes to the increase in red cell alloimmunization rate compared with the general population. Interestingly, by molecular genotyping, it was found that SCD patients have a high frequency of polymorphisms that can result in red cell alloimmunization even when serologically matched red cells are transfused. In addition, the endothelial damage and chronic inflammatory state associated with SCD have been hypothesized to cause synergy in red cell alloimmunization. Genetic factors predisposing SCD patients to red cell alloimmunization have been studied, and patients with HLA-B35 have a sixfold higher likelihood of making red cell alloantibodies compared with SCD patients lacking HLA-B35. The Genome-Wide Association Studies (GWAS) currently being pursued may clarify the role of genetic factors. Interestingly, the rate of alloimmunization was not proportionally observed in patients receiving massive transfusion with un-crossmatched RBCs. This observation may be due to transient immunosuppression in the setting of severe physiologic stress or by immune modulation due to the overwhelming number of foreign RBCs transfused. This phenomenon was also shown in pediatric SCD patients receiving RBC exchange. On rare occasions, solid organ transplant can also be a source of red cell alloimmunization as it may expose the recipient to residual donor red cells with foreign antigens, despite immediate saline perfusion to rinse blood from the organ. Clinical hemolysis may be observed, but severe hemolytic complications are more likely a result of passenger lymphocytes that are capable of mounting an anamnestic response to antigen-positive recipient red cells (passenger lymphocyte syndrome). From the knowledge gained through observational studies, the risk of red cell alloimmunization seems to be associated with both red cell exposure and host immune responses. However, the complete pathophysiology still remains to be determined.

Molecular Pathophysiology

The exact cause of human RBC alloimmunization under myriad clinical circumstances is multifactorial and difficult to accurately identify. Thus, reductionist animal model–based studies will be needed to investigate the mechanisms and identify the specific etiologies of this clinical entity. Given the well-defined genetic background, ready availability of a large number of participants, ability to adapt to many genetic manipulations, and largely conserved lineage-specific genes in the mouse immune system, mouse models are ideal to investigate this complex clinical entity. For example, transgenic human Rh, Kell, and Duffy antigen-expressing mice have been generated to study the interaction with their cognate alloantibodies. In addition, human hemolytic disease of the fetus and newborn (HDFN) associated with alloantibody against the Kell antigen has been closely recapitulated in pregnant transgenic Kell mice. Unlike the HDFN associated with alloantibody against the RhD antigen that can be prevented with the administration of Rh immune globulin, HDFN associated with alloantibody against the Kell antigen still lacks effective prevention. Therefore, this anti-Kell mouse model will be useful in revealing the mechanism of alloimmunization against the Kell antigen.

The transgenic murine model of SCD revealed that the sickle cell genetic mutation alone was not sufficient to independently cause RBC alloimmunization. One study further suggests the critical roles of environmental factors involved in this immune response. Indeed, other mouse model studies have found that viral analog-induced inflammation (e.g., polyinosinic polycytidylic acid, or poly:IC) can independently enhance RBC alloimmunization. Furthermore, experimental mice transfused in the absence of inflammation developed immune tolerance against the transfused foreign red cell antigens as compared with control mice in the presence of poly:IC. This observation is supported by the fact that most transfused individuals without infections do not make alloantibodies to nonself red cell antigens. Also, exogenous inflammatory factors accumulated during RBC storage (storage lesion) were found to enhance sensitization to foreign RBCs leading to a more than 10-fold increase in alloantibody production. This concept has not yet been tested in prospective controlled clinical trials.

While animal models are able to provide the reductionist view of red cell alloimmunization and can serve as a platform to study the mechanism of red cell alloimmunization, the study conclusions may have limited general applicability. For example, the transgenic SCD mouse model has inherent differences in disease manifestations (e.g., massive splenomegaly and large vessel vasculopathy) that are not observed in human SCD patients. In addition to the interspecies genetic variation, the homogeneous nature of the experimental mouse's genetic background may not fully capture the true pathophysiology of red cell alloimmunization in the human population. Nevertheless, mouse models provide a molecular view of the disease pathogenesis and generate many new hypotheses to further elucidate the mechanism of red cell alloimmunization.

Red Blood Cell Alloimmunization Mitigation Strategies

Blood transfusion is one of the most common therapies provided in a hospital, and millions of blood products are transfused every year worldwide. Therefore, a carefully planned strategy to prevent red cell alloimmunization is urgently needed. Reducing red cell alloimmunization can occur in three areas: blood collection/manufacturing, hospital transfusion services, and through patient care. At the blood center, prestorage leukoreduction can effectively remove more than 99.99% of the original WBCs. This process minimizes the inflammatory or "danger" signals infused into recipients at the time of foreign red cell antigen exposure and thus may reduce subsequent alloimmunization. Some blood centers have also begun to provide non-ABO red cell antigen typing on RBC units to minimize transfusing RBCs with mismatched red cell antigens. Clinical interventions have also been proposed to reduce red cell alloimmunization risk. Surgical splenectomy was shown in mouse models and observed in transfusion-dependent patients (e.g., thalassemia) to reduce the alloimmunization rate; however, this procedure is not as effective if the initial antigen exposure occurred prior to spleen removal. Since sickle cell patients develop asplenia at early ages, this finding may also not be relevant to the high incidence of alloimmunization in sickle cell anemia. Immunosuppression can also theoretically retard the red cell alloimmunization rate. However, one must consider the adverse clinical impact of these drugs. More studies on drug types and dosages are needed to refine this strategy. Finally, blood bank practice plays a daily pivotal role in preventing red cell alloimmunization in hospital patients. Molecular/genetic typing can permit red cell antigen matching at a higher resolution and precision than traditional serologic red cell antigen typing. This additional testing is particularly helpful in patients with hemoglobinopathies or high titer warm autoantibodies, who are especially vulnerable to red cell alloantibody formation. Expert hematology guidelines now strongly recommend extended molecular RBC genotypes in all SCD patients with subsequent prophylactic RBC matching for Rh and K1 antigens to prevent alloimmunization from transfusion.

ALTERNATIVES TO ALLOGENEIC RED CELL TRANSFUSIONS

There are many alternatives to standard allogeneic red cell transfusions for a patient requiring elective surgery (Table 112.4). Potential alternatives include banking autologous units before the surgery, acute normovolemic hemodilution, pharmacologic therapies (i.e., erythropoietin or fibrinolysis inhibitors), perioperative salvage, virally inactivated donor red cells, or blood substitutes. All current options have their own unique benefits and drawbacks, and some of these alternatives are not yet available. In cases where an emergency transfusion is needed, the first three options would not be possible as they all require significant planning. Only virally inactivated components and red cell substitutes (both of which are still works in progress) would be available for unanticipated transfusion needs.

Autologous Blood Transfusion

Advantages of Autologous Blood Transfusion

The substitution of autologous blood components for those collected from other (allogeneic) donors eliminates transfusion-transmitted diseases such as viral hepatitis and acquired immunodeficiency syndrome. Immunologic complications related to the transfusion of foreign cells, including hemolysis and febrile reactions to WBCs, are also prevented. Other advantages, though possible, are less clearly established. For example, erythropoiesis may be sufficiently stimulated in the repeatedly bled autologous donor to hasten recovery from postoperative anemia. Intraoperatively salvaged red cells are spared the acquired membrane defects ("storage lesion") and 2,3-DPG deficiencies of refrigerated red cells.

TABLE 112.4 Alternatives to Standard Allogeneic Transfusions

Hemodilution
Intraoperative autologous transfusion
Perioperative blood salvage
Lower transfusion trigger
Pharmacologic therapies
Pathogen inactivation
Red cell substitutes
Stem cell derived red blood cells

An important drawback to these techniques is their increased expense in contrast to the simpler allogeneic transfusions they replace. In addition, the availability of autologous components may result in their use in situations where transfusion might not have otherwise been considered. For orthopedic and urologic elective surgeries, the recent advent of less invasive intraoperative procedures has led to reduced need for transfusion. Patients with suboptimal compensatory erythropoiesis and donation-induced anemia at the time of surgery are also more likely to be given transfusions. Based upon the current level of viral safety in blood components in the developed world, the use of autologous blood has dropped significantly from times when viral testing was not available or reliable.

Preoperative Autologous Blood Collection

The typical volunteer allogeneic blood donor is allowed to give one unit of blood no more than once every 8 weeks to prevent iron deficiency. However, provided that bone marrow erythropoiesis can be stimulated and satisfactory iron supplies maintained, blood can be collected as frequently as once a week from an autologous donor. Although the shelf-life of refrigerated RBCs is limited to 42 days, frozen storage for up to 10 years is possible at below −65°C using glycerol as a cryopreservative.

From a cardiovascular standpoint, phlebotomy is well tolerated by a variety of seemingly high-risk donors, including the elderly, children, pregnant women, and patients with coronary artery disease. By contrast, anemia frequently develops during the donation interval and limits the number of autologous units that can be collected. In addition to marginal iron stores, erythropoietin levels often do not increase during the donation interval, probably because the hematocrit level of most donors is not allowed to fall to less than 30%. This situation may be improved by the administration of the recombinant erythropoietin to autologous donors. Since many procedures are now performed using laparoscopy or other techniques to limit blood loss, the demand for predeposit autologous transfusion support has fallen in recent years.

Autologous blood has been safely collected from women during pregnancy for use during childbirth. Nevertheless, the transfusion rate at delivery is quite low (<2.5% in many institutions) and most autologous donations are unused. Long-term (frozen) storage of autologous RBCs in the absence of a planned transfusion episode is largely ineffective and expensive.

Intraoperative Blood Salvage

Cell salvage occurs in three phases: collection, washing, and reinfusion. RBCs are collected from the operative field using a dedicated double lumen suction device. One lumen suctions blood from the operative field and the other lumen adds heparinized saline to the salvaged blood. The anticoagulated blood then passes through a filter and is collected in a reservoir. If less than 1 L of blood is collected, further processing is foregone and the collected blood is discarded.

In most circumstances, the contents in the bag can be washed to remove free Hb, surgical irrigation solutions, and other debris. Instruments are available that include both a reservoir for collecting salvaged blood and a centrifugal washer. Large aliquots (>500 mL) can be fully washed in as little as 3 minutes. As a result of this speed, autologous blood salvage has become practical in situations in which blood loss may be extremely rapid, such as trauma or liver transplantation.

The hematocrit level of unwashed blood is typically low because of dilution from irrigating surgical fluids and some degree of mechanical hemolysis. Free Hb levels are sometimes greater than 1000 mg in unwashed blood, and hemoglobinemia and hemoglobinuria may occur after the transfusion, although renal sequelae are surprisingly

TABLE 112.5 **Autologous Blood Salvage Systems[a]: Characteristics of Collected Blood**

System	Hardware	Software	Hematocrit	Free Hemoglobin	Platelet Count	Coagulation Factors	Fibrin Degradation Products
Collection without washing	Rigid plastic container	Plastic bag	Low (25%)	Very high (200 mg%)	Low (100,000/mm^3)	Low (35%–75%)	High (300 mg%)
Collection followed by washing	Integral or separate blood cell processor	Disposable plastic bowl and tubing	High (60%)	Low (<50 mg%)	Very low (10,000/mm^3)	Absent (0%)	Absent (0%)

[a]Typical results of laboratory tests are shown. Transfusion of large volumes of salvaged blood results in similar alterations in these tests in the recipient.

low. Despite this evidence of red cell injury, the survival rate of ^{51}Cr-labeled salvaged cells is normal in most patients studied.

There are many potential complications associated with cell salvage, such as nonimmune hemolysis, air embolus, febrile nonhemolytic transfusion reactions, mistransfusion, coagulopathy, and contamination with drugs. Transfusion of salvaged blood has resulted in coagulation abnormalities, including hypofibrinogenemia, prolonged prothrombin time and partial thromboplastin time, elevated fibrin degradation products, and thrombocytopenia. These coagulation abnormalities most likely reflect the characteristics of the salvaged blood itself, which, after exposure to serosal surfaces, becomes deficient in coagulation factors and platelets and, in the case of unwashed blood, has high levels of fibrin degradation products (Table 112.5). Coagulation abnormalities can also occur when extensive red cell salvage has been given without adequate plasma or platelet support.

Fat, fibrin, bone fragments, and microaggregates often contaminate salvaged autologous blood. However, infusion of unwashed blood has not been proved harmful in either animals or humans, possibly because routine blood filters remove most particulate material. Other contaminants, such as heparin, topical antibiotics, hemostatic agents, and biologic substances such as tissue enzymes, can be at least partially removed by washing. Complete removal of bacteria is also not possible, even when the salvaged blood is washed with antibiotics. Thus, collection of blood from a contaminated site (e.g., with intestinal contents) is usually considered to be contraindicated; in fact, manufacturers contraindicate the use of cell salvage in cases where there is potential contamination of salvaged blood with enteric contents. However, in recent years, this viewpoint has been reconsidered as studies have found that the autotransfusion of microbiologically contaminated salvaged blood has demonstrated no adverse outcomes or increase in postoperative infectious complications. Tumor cells have been found in blood salvaged during cancer operations and thus many practitioners consider cancer another contraindication. Others believe that filtration would remove salvaged tumor cells.

Approximately one-half of the blood lost during surgery can be salvaged. The rest is usually irretrievably absorbed in drapes and sponges or damaged during collection. The use of salvaged autologous blood has been associated with a 50% reduction in allogeneic blood use in orthopedic procedures such as spinal surgery and hip replacement and is also effective in vascular surgical procedures such as aortic reconstruction. Autologous salvage has been a useful adjunct in the treatment of some Jehovah's Witnesses whose literal acceptance of the Bible includes abstention from routine allogeneic blood transfusions.

Both the canister systems and RBC processors used to collect intraoperative autologous blood can also be used to collect postoperative blood drainage, such as that from the mediastinum after open-heart surgery, from the knee or hip after orthopedic procedures, or from the peritoneal cavity after hepatic injury. Because blood salvaged from a serosal cavity has little residual fibrinogen and platelets, clotting is not a problem, and the addition of anticoagulants is usually unnecessary. Shed mediastinal blood after open-heart surgery contains high levels of cardiac muscle enzymes, especially creatine kinase, as well as lactate dehydrogenase from hemolyzed RBCs. Therefore, reinfusion of shed blood results in elevated levels of both enzymes that can confound the diagnosis of myocardial infarction (MI) in the postoperative period. Reinfusion of shed mediastinal blood has been shown to reduce the need for allogeneic transfusions.

Hemodilution

The collection of autologous blood at the onset of surgery for later reinfusion at the end of the procedure was first suggested in open-heart operations, in which it was hoped that a supply of platelets undamaged by exposure to the membrane oxygenator might reduce the incidence of coagulopathies. Hemodilution itself reduces RBC loss: a patient with a hematocrit level of 45% and 2 L blood loss during surgery loses roughly 900 mL of RBCs, but one with a hematocrit level of 20% from hemodilution loses only 400 mL of RBCs. Hemodilution is less expensive to accomplish than preoperative autologous blood donation and may be the only option available when surgery is performed in other than elective settings. Proponents claim that the induced anemia may even be beneficial to the patient, in that oxygen delivery at a hematocrit level of 30% is enhanced by an increased cardiac output resulting from the decreased blood viscosity. Other advantages of hemodilution over predeposit autologous transfusion are the provision of fresh red cells along with plasma and platelets that may be important in maintaining hemostasis.

Reductions in allogeneic blood needs have been reported after marked intraoperative hemodilution (after the hematocrit is lowered by 50%). More modest hemodilution (e.g., removal of 2 units of blood at the beginning of surgery) is also beneficial according to some investigators, but the amount of red cells saved is small.

BLOOD SUBSTITUTES

The search for blood substitutes began when our early scientific ancestors tested alternatives to human blood, including animal blood and Hb solutions, milk, and wine. Further work revealed that human and bovine hemosylates caused renal dysfunction in human recipients. The suspected cause of this nephrotoxicity was the stromal lipid component of the RBC membrane. The logical next step in the search for the ideal substitute was the development of stroma-free Hb (Hb tetramer). Unfortunately, in 1978, Savitsky et al. demonstrated renal dysfunction, hypertension, and abdominal pain using stroma-free Hb in healthy volunteers. It was hypothesized that these adverse events were due to the instability of the Hb tetramer. Since then, efforts have been made to produce stabilized products with desirable oxygen off-loading characteristics and extended intravascular retention times.

Today, the United States blood supply is increasingly safe and has sufficient capacity to meet most patient needs. There is room for considerable improvement, however, in supply levels and risk reduction. The shrinking donor pool (owing to lack of willingness and/or ability) and the increasing transfusion requirements of an aging population may lead to a shortage of blood products. The continuous battle against emerging infectious diseases underscore the risk of a tainted

TABLE 112.6 The Ideal Red Cell Substitute

Delivers oxygen (and maybe enhances delivery)
Does not transmit disease
Does not have immunosuppressive effects
Available in abundant supply
Universally compatible (no need to type and crossmatch)
Prolonged shelf-life and stable at a range of temperatures
Similar in vivo half-life to the RBC
Available at a reasonable cost
Easy to administer
Able to access all areas of the human body (including ischemic tissue)
Effective on room air or ambient conditions

RBC, Red blood cell.

blood supply and depletion of transfusion resources. Theoretically, the ideal red cell substitute would solve both of these issues (Table 112.6). There have been many attempts to develop red cell substitutes in the past, but no product has been able to fulfill all of the presented criteria or meet the FDA requirements of purity, potency, and safety.

RED BLOOD CELL SUBSTITUTES

It is important to differentiate between "blood substitutes" and red cell substitutes. Red cell substitutes are oxygen carriers and do not replace all components and functions of blood, for example, coagulation factors and WBCs. Blood substitutes also have a short intravascular survival limiting their potential efficacy as a replacement for red cell transfusions. There remains one category of oxygen carriers that still shows promise as RBC substitutes: Hb-based oxygen carriers (HBOCs).

Hemoglobin-Based Oxygen Carriers

As RBCs age and degrade, the stroma and unmodified Hb released can lead to various adverse effects in the transfused recipients. Therefore, the HBOCs that were most recently in clinical development were stroma-free and engineered to produce desirable oxygen dissociation characteristics as well as an adequate in vivo half-life with minimal toxicities. Stroma-free Hb has a very high oxygen affinity compared with native Hb in a RBC because of a lack of 2,3-DPG. Furthermore, the Hb tetramer is such a small molecule that the kidney rapidly removes it.

Four different methods have been suggested to avoid toxicities: stabilization, polymerization, conjugation, and Hb vesicles. HBOCs can be prepared from different Hb sources (e.g., bovine RBCs or recombinant Hb harvested from bacteria/yeasts). However, the safety concerns of using Hb from nonhuman sources, such as the potential for transmitting diseases, immunogenicity, and toxicities have not been fully addressed. While one of the commercially available HBOCs (e.g., bovine-derived oxyglobin, HBOC-301) is approved for veterinary use, there is no HBOC product approved for clinical use although several products are in clinical development phases. A large meta-analysis by Natanson et al. in 2008 identified 16 randomized controlled trials in which adult patients received HBOCs therapeutically. The analysis reviewed the association between HBOCs and the risk of MI and mortality in clinical trials. The study included five different HBOCs in the analysis and reported a 30% increase in the risk of death and a threefold increase in the risk of MI when all HBOC trials were pooled. The meta-analysis has been criticized for including trials of varying HBOC products performed on heterogeneous patient populations in different settings with different controls. The authors of the meta-analysis criticized the United States government oversight, as well as the transparency and timeliness in reporting the results of the HBOC clinical trials. The editorial that accompanied the publication in the *Journal of the American Medical Association* made a recommendation that further phase III trials of HBOCs should not be conducted until the mechanisms and potential toxicities are better understood. The effects may be due to the interaction of Hb and nitric oxide (NO), a concern not fully appreciated in the early days of blood substitute research, but potentially addressed by the expansion of knowledge about NO and mitigating its effects. Although some HBOCs are still being investigated, there are no licensed products in the United States.

Potential Clinical Applications

RBC substitutes have many potential applications. One of the most compelling needs would be the use for rapid resuscitation during military and civilian traumas. In developing a specific plan to avoid the consequences of blood unavailability after national disasters involving large-scale injuries, blood substitutes could play a key role as an immediate treatment option. In addition to these acute emergency situations, there is a wide range of less urgent applications where oxygen carriers might provide a viable solution to difficult situations, including supporting solid organ perfusion during transport/storage, augmenting perioperative hemodilution, transfusion of patients who refuse human blood components because of religious beliefs (e.g., Jehovah's Witnesses), transfusion of patients with rare blood types or antibodies to high incidence antigens, transfusion in patients with autoimmune hemolytic anemia in whom it is difficult to detect underlying antibodies, and reducing alloimmunization risk in patients receiving frequent transfusions. Since blood transfusion therapy is not available to handle some of these indications, there remains an unmet medical need for a safe and efficacious RBC substitute.

Red Blood Cells Derived From Stem Cells

Due to the threat of future blood shortages, the possible shortening of RBC storage, and unlikely availability of RBC substitutes in clinical use, a new source of RBCs is needed. Blood substitutes will not answer this need in the near future. The generation of RBCs derived from stem cells could meet this need, and this method is currently under development by researchers worldwide.

Umbilical cord blood is an accessible source of stem cells with proliferative capacity; however, the proliferation is not infinite, requiring a system of production in batches. Neildez-Nguyen et al. first reported the possibility of converting umbilical cord stem cells into erythroid progenitors that can continue to mature into terminally differentiated RBCs in vivo. Giarratana et al. subsequently demonstrated that adult mobilized hematopoietic stem progenitor cells can also be differentiated into RBCs and found that the survival of the cultured RBCs was similar to that of native RBCs. Under optimized expansion and differentiation conditions, Giarratana et al. reported that they were able to generate 4 to 30 million RBCs from one hematopoietic stem progenitor cell obtained from apheresis donors. While this expansion scheme could be adequate to generate clinically useful transfusable RBCs, it may not justify the donor risks (e.g., G-CSF–mobilized apheresis collection) for the sole purpose of RBC production. Stem cells cultured from umbilical cords would necessitate the use of cord blood banks and would still be dependent on human donation. In addition, cord cells produce fetal Hb with a higher tendency to denature and to cause membrane damage compared with adult Hb. Alternatively, embryonic stem cells and induced pluripotent stem cells (iPSCs) can be obtained, generated, then maintained indefinitely in culture, thus providing an unlimited source of cells. Like embryonic stem cells, iPSCs are capable of in vitro self-renewal and differentiation into cell types from all germ layers. However, they possess an advantage over embryonic cells in that they pose no ethical dilemma and can be selected based on known phenotypes. Researchers have been able to demonstrate that iPSCs can differentiate into terminally mature and fully functional red cells. More recently, Heshusius et al. have optimized large-scale cultures of RBCs from peripheral blood mononuclear cells using a good manufacturing practice (GMP) grade culture medium. The cultures yield a 10^7-fold increase in erythroblasts in 25 days and can be differentiated to RBCs in 12 days with greater than 90% enucleation. Furthermore, the cultured RBCs synthesize adult Hb and the expected blood group antigens.

A number of challenges must be overcome before we have an unlimited supply of clinical grade RBCs. The ideal choice for the initial cell type (e.g., hematopoietic stem cell and erythroblast) remains to be determined. The method of reprogramming the cells must be established to avoid the risk of potential mutation and tumor development (although this is less of an issue for red cells as they are enucleate and can be safely irradiated) while still ensuring the functionality of the end product. Finally, the use of GMP conditions for mass production within a reasonable amount of time and at a reasonable cost seems to be the greatest hurdle to date. The current challenges in utilizing iPSCs to generate RBCs are the inefficiency in erythroid commitment and the suboptimal cellular amplification. A number of strategies are under development to solve this crucial problem. Until mass amplification is possible, the iPSCs could be developed, not as an unlimited supply, but as a source of cells expressing a rare blood group used to treat allo-immunized patients with rare blood types. Currently, the available methods for ex vivo manufacturing of RBCs for clinical use are expensive and unrealistic.

CHAPTER 113

CLINICAL CONSIDERATIONS IN PLATELET TRANSFUSION THERAPY

Richard M. Kaufman

PLATELET COLLECTION AND MANUFACTURING

Platelet components are either prepared from whole blood donations (platelet concentrates) or are collected by apheresis (single donor platelets). In the United States, whole blood–derived platelet concentrates are produced using the platelet-rich plasma (PRP) method. First, a whole blood unit is separated by gentle centrifugation (slow spin) into red blood cells (RBCs) and PRP. The PRP is then centrifuged a second time (hard spin) to isolate one platelet concentrate plus one unit of plasma. Each platelet concentrate contains approximately 5.5×10^{10} platelets suspended in a plasma volume of approximately 50 mL. In Europe and Canada, the alternative buffy coat method is used to produce platelet concentrates. To prepare an adult dose of platelets for transfusion, four to six platelet concentrates are pooled together.

Apheresis platelet units are collected from a single platelet donor by continuous flow centrifugation using an automated device. A high volume of whole blood is processed through the machine, and the platelets are retained in a sterile collection bag. According to AABB (formerly, the American Association of Blood Banks) standards, an apheresis platelet unit should contain a minimum of 3×10^{11} platelets, a dose that is approximately equivalent to five pooled platelet concentrates. Current devices allow many different combinations of blood products to be collected during a single apheresis donation, such as 1 unit of platelets plus 1 unit of RBCs. Apheresis platelet units generally contain less than 1×10^6 white blood cells (WBCs) per unit; thus they meet the current AABB definition for leukoreduced blood products ($<5 \times 10^6$ WBCs/unit). Although apheresis platelets cost more to produce than whole blood–derived platelet concentrates, they have become increasingly popular. In the United States in 2015, approximately 2 million therapeutic doses of platelets were provided as apheresis platelets; in contrast, only approximately 200,000 equivalent doses of whole blood–derived platelet concentrates were distributed.

Apheresis platelets provide limited advantages over whole blood–derived platelet concentrates. Radiolabeling studies indicate that apheresis platelets circulate longer in vivo than pooled concentrates, most likely reflecting gentler handling and less platelet activation during collection. Recipients of apheresis platelets are exposed to fewer donors per transfusion (one donor versus four to six as with a pool of platelet concentrates), so in principle, apheresis platelets should pose a lower risk of viral transmission than whole blood–derived platelets. However, given that the per-unit transfusion-transmission risks for human immunodeficiency virus (HIV) and hepatitis C virus have been reduced to less than 1 per 1,000,000, the viral safety advantage of apheresis platelets over whole blood–derived platelets is marginal. Data from surveillance culture studies suggest that apheresis platelets may be less likely than platelet concentrates to become contaminated with bacteria. At one time, it was predicted that apheresis platelets would be less likely than pooled concentrates to provoke platelet alloimmunization by virtue of exposing recipients to fewer unique donor human leukocyte antigens (HLAs). However, this hypothesis was not confirmed empirically. Although they express surface HLA class I antigens, platelets appear to be rather poor immunogens. HLA alloimmunization to platelets primarily appears to be triggered by contaminating WBCs within a platelet unit. Thus alloimmunization is not platelet dose dependent, and simply providing leukoreduced platelet units prevents most cases of immune-mediated platelet refractoriness. When platelet refractoriness does occur, it is often in multiparous women, who were initially sensitized to foreign (paternal) HLA antigens in previous pregnancies.

PROPHYLACTIC PLATELET TRANSFUSION

Most platelet units are transfused to prevent bleeding in nonbleeding patients, rather than to treat active bleeding. Before 1960, platelet transfusions were not widely available, and death from hemorrhage was common among patients with leukemia who received chemotherapy. In 1962, Gaydos and colleagues[1] published a seminal study demonstrating an inverse relationship between days with bleeding and platelet count. After this study was published, prophylactic platelet transfusion rapidly became standard practice. Notably, based on their data, no specific platelet transfusion trigger was suggested by the authors. Regardless, a platelet count of 20,000/μL was widely adopted at the time as the standard prophylactic platelet transfusion trigger.

Later studies suggested that a lower transfusion trigger would be as effective as a trigger of 20,000/L. For instance, Slichter and Harker[2] performed RBC radiolabeling studies in thrombocytopenic patients who were not receiving platelet transfusions. They demonstrated that only patients with platelet counts less than 5000/L had significantly elevated fecal RBC loss. Years later, several clinical studies directly challenged the 20,000/L trigger. Platelet transfusion triggers of 10,000/L versus 20,000/L were compared directly in three randomized prospective studies of patients with acute leukemia.[3–5] These studies, as well as a nonrandomized prospective trial,[6] did not show an increased incidence of bleeding when a trigger of 10,000/L is used. More recently, the Platelet Dosing (PLADO) trial demonstrated that the risk of bleeding among patients with hypoproliferative thrombocytopenia increased only at platelet counts less than 6000/μL.[7] As shown in Fig. 113.1, the risk of spontaneous bleeding was equivalent between platelet counts of 6000/μL and 80,000/μL.

Severe hemorrhage in the setting of therapy-related hypoproliferative thrombocytopenia is now quite rare. Given the substantial changes in both chemotherapy and the supportive care of patients with hematologic malignancy that have occurred over the past several decades, two randomized controlled trials examined whether routine platelet prophylaxis still provides a clinical benefit. In the study by Wandt and colleagues,[8] patients receiving chemotherapy or undergoing autologous hematopoietic stem cell transplantation (HSCT) were randomly assigned to receive platelet transfusions only when bleeding occurred, or standard prophylactic platelet transfusions for a morning platelet count at or less than 10,000/μL. Grade 2 or higher bleeding occurred in 42% of patients receiving therapeutic platelet transfusions only, versus 19% in patients receiving platelet prophylaxis ($P < .001$). There were significantly more intracerebral hemorrhages in the no-prophylaxis group (7% vs. 2%, $P = .01$), and there were two deaths due to bleeding in the no-prophylaxis group compared with zero in the prophylaxis group. In the Trial of Prophylactic Platelets,[9] a similar population of patients was randomized to no prophylactic platelet transfusions or routine prophylaxis. Grade 2 or higher bleeding occurred in 50% of patients in the no-prophylaxis group versus 43% in the prophylaxis group ($P = .06$ for noninferiority). In this study, there were no deaths due to bleeding. In both trials, bleeding occurred more frequently among patients being treated for acute leukemia versus autologous stem cell transplant recipients. Overall,

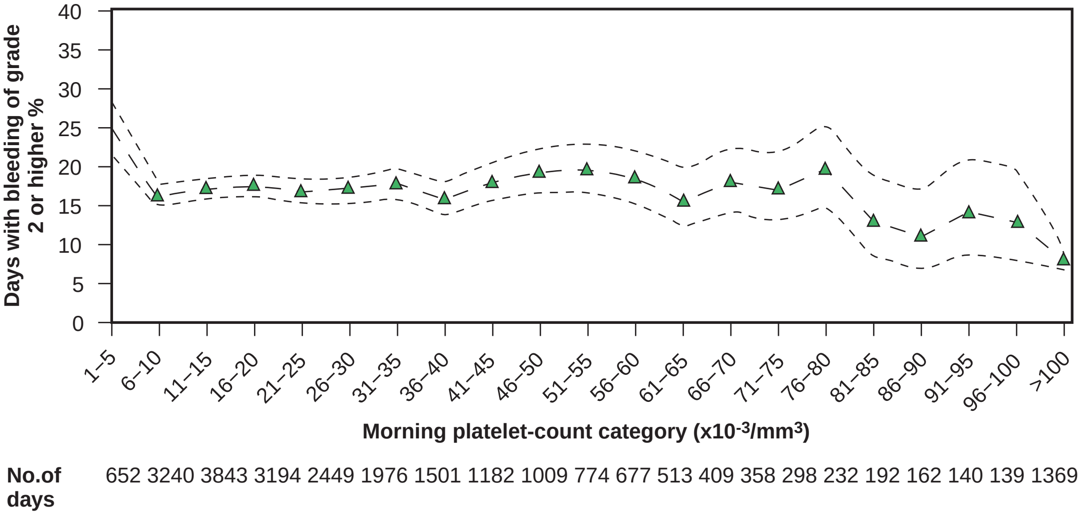

Figure 113.1 RELATIONSHIP BETWEEN PLATELET COUNT AND SPONTANEOUS BLEEDING AMONG PATIENTS WITH THERAPY-INDUCED HYPOPROLIFERATIVE THROMBOCYTOPENIA. The percentage of days that adult or pediatric patients with hematologic malignancy enrolled in the Platelet Dosing (PLADO) trial had grade 2 or higher bleeding is shown as a function of morning platelet count. The 95% confidence intervals are shown as dashed lines. The bleeding risk was equivalent for platelet counts between 6000 and 80,000/μL.[12]

the results of these trials support the continued use of prophylactic platelet transfusions for patients with hematologic malignancy and therapy-induced hypoproliferative thrombocytopenia.[10] However, using a no-prophylaxis strategy specifically for adult autologous stem cell transplant recipients has been endorsed by the American Society of Clinical Oncology (ASCO).[11]

Prophylactic platelet transfusions are mainly given in the setting of oncology, but they are also used to prevent bleeding in thrombocytopenic neonates. Notably, a multicenter randomized controlled trial of 660 preterm infants found that using a high platelet count threshold for administering prophylactic platelet transfusions (50,000/μL) was associated with significantly higher mortality or major bleeding events than using a low threshold (25,000/μL).[12]

Prophylactic Platelet Dosing

There are currently thought to be two distinct clearance mechanisms for platelets. Most platelets undergo senescence after circulating in the peripheral blood for 8 to 10 days. But there is also evidence for a second clearance route in which there is a fixed daily loss of platelets that occurs independent of platelet age. Platelets exiting the circulation via this second route are postulated to function in maintaining vascular integrity. In principle, a low dose of platelets could be used to meet this daily requirement. This hypothesis was tested by the 2010 PLADO trial. A total of 1272 patients receiving HSC transplantation or chemotherapy were randomly assigned to receive low-, medium-, or high-dose platelets for a morning count of 10,000/μL or lower. The risk of spontaneous bleeding was not increased until patient platelet counts decreased to 5000/μL or lower. No differences were observed in bleeding rates among the three treatment groups, supporting the concept that few platelets are required to maintain hemostasis. Although significantly fewer total platelets were transfused to patients in the low-dose group, platelet transfusions were required more frequently.[7]

Prophylactic Platelets for Invasive Bedside Procedures

To date, there have been no large randomized controlled trials evaluating the need for platelet prophylaxis before invasive bedside procedures such as lumbar puncture. However, retrospective data provide reassurance that moderate thrombocytopenia does not pose a serious risk for performing such procedures. Howard et al.[13] reviewed the records of 956 consecutive pediatric patients with newly diagnosed acute lymphoblastic leukemia who underwent lumbar puncture. No serious hemorrhagic complications were observed after 5223 lumbar punctures, including 170 procedures that were done when the platelet count was 11,000 to 20,000/μL. The authors concluded that prophylactic platelet transfusion was unnecessary in patients with platelet counts greater than 10,000/μL. Lumbar punctures were performed in only 29 patients with platelet counts of 10,000/μL or less, making it difficult to assess the risk of bleeding in patients with very low platelet counts. A similar, albeit much smaller, retrospective study examined the same issue in adult patients with acute leukemia.[14] No hemorrhagic complications were observed after 195 lumbar punctures, including 35 that were done with platelet counts of 20,000 to 30,000/μL. With very limited published data available on severely thrombocytopenic adults, AABB has suggested 50,000/μL as a minimum safe platelet count for lumbar puncture in adult patients. For central venous catheter placements, AABB has suggested 20,000/μL as a minimum safe platelet count, based on multiple observational studies.[10] Relatively few studies have been published to date addressing the question of a safety minimum platelet count for other types of bedside procedures (thoracentesis, paracentesis, etc.)

Prophylactic Platelets for Major Surgical Procedures

There are currently no data from randomized trials addressing the question of what constitutes an adequate platelet count before surgery. However, retrospective studies suggest that patients with platelet counts of 50,000/μL or higher are not at excess bleeding risk during surgery. Bishop and colleagues[15] reported a series of 95 patients with acute leukemia who underwent 130 surgical procedures with platelet counts of less than 50,000/μL. Intraoperative blood loss exceeded 500 mL in only 7% of cases. No relationship was seen between the preoperative platelet count and surgical blood loss. These data suggest that prophylactic platelet transfusions need not be administered before surgery when the preoperative platelet count is at least 50,000/μL. This rule of thumb is thought to apply to most types of surgery (cardiac, orthopedic, and so on). However, for a few types of surgeries, requiring a higher platelet count (70,000 to 100,000/μL) is traditional, although no published data currently exist either to support or refute this approach. These settings include neurosurgery, retinal surgeries, and other procedures in which the risk is not that the patient may exsanguinate but rather that even a minor bleed might cause clinically significant damage in a vulnerable vital structure such as the brain.

Platelets to Treat Bleeding

High-quality data to guide platelet use in the setting of active bleeding are lacking. A small randomized controlled trial in patients on antiplatelet medication who suffered intracerebral hemorrhage found worse outcomes among patients transfused with platelets compared with patients receiving standard care only.[16]

ADVERSE EFFECTS OF PLATELET TRANSFUSION

Infectious Risks

Platelets are associated with essentially the same range of infectious pathogens as other blood components, but septic transfusion reactions caused by bacterially contaminated units comprise a unique risk of platelet transfusion. Over time, improvements in donor screening virtually eliminated the risk of transfusion transmission of hepatitis B virus, hepatitis C virus, and HIV. The risk of septic transfusion reactions remained fairly constant over this same period, so eventually, platelet bacterial contamination became, by default, the most frequent infectious risk of transfusion. Unlike other blood components, which are stored either refrigerated or frozen, platelets are stored at room temperature. The reason is that if platelets are refrigerated before transfusion, they are cleared rapidly from the recipient's circulation.[17] Although room temperature storage allows transfused platelets to circulate in vivo, it has the downside of promoting bacterial growth. Because of this risk, platelet storage is limited to only 5 to 7 days, making platelet inventory management extremely challenging. It has been observed that platelets stored under refrigeration (4°C) demonstrate better hemostatic function than room temperature platelets in most in vitro assays. Future clinical trials will determine whether administering refrigerated platelets leads to improved outcomes among patients with acute bleeding. Other alternatives to standard platelets (e.g., frozen platelets, artificial platelets) are also being explored.

In the 1990s, numerous studies demonstrated that contaminating bacteria, usually representing skin flora from the donor, could be cultured out of approximately 1 of 3000 platelet units. Clinically apparent septic transfusion reactions were thought to occur after approximately 1 of 25,000 platelet transfusions, although there is considerable uncertainty around this point estimate. In response to the issue, the US Food and Drug Administration (FDA) in 2019 issued a final guidance requiring enhanced bacterial detection/prevention for platelet units. A common approach is to use automated culture systems (BacT/ALERT, Biomerieux) to detect bacterial contamination before platelets are released for clinical use. Rapid, point-of-issue tests that can be used to test the sterility of a platelet unit just before issue have also been developed but are not widely used due to issues of logistics and cost. Pathogen reduction systems represent the strongest approach to the problem of platelet bacterial contamination. These systems use photoactivated reagents such as amotosalen or riboflavin plus ultraviolet (UV) light to provide up to 6 logs of killing of spiked virus or bacteria within 1 unit of platelets. Such systems have been used in Europe and elsewhere, and in 2015, a pathogen reduction system for platelets and plasma was licensed for use in the United States. These technologies are highly effective for ensuring the sterility of platelet units. Platelet increments are a bit lower when pathogen-reduced platelets are administered, but clinical outcomes in patients receiving platelet prophylaxis are similar.

Allergic and Febrile Nonhemolytic Transfusion Reactions

The typical RBC unit contains approximately 20 mL of plasma. Platelet units contain far more plasma, approximately 200 mL on average. There are multiple potential adverse effects associated with this large plasma content. Indeed, in the PLADO trial, higher platelet doses were associated with significantly increased risk of transfusion-related adverse events.[18] Febrile nonhemolytic reactions, defined as an increase in temperature of more than 1°C, are the most common reactions seen after platelet transfusion. In a classic study, Heddle and colleagues[19] demonstrated that the plasma component of platelet units, rather than the cellular component, causes most reactions. Cytokines that accumulate during product storage have been implicated. Allergic transfusion reactions are the second most-common type of adverse event associated with platelet transfusion.[18] Allergic reactions to blood products occur when the recipient has a preexisting allergy to a plasma protein component. Allergic reactions range from mild, uncomplicated urticarial reactions (most common) to full-blown anaphylaxis. Platelet additive solution (PAS) platelet units are those in which a preservative solution replaces most of the residual plasma. Using PAS platelets has been shown to reduce the risk of allergic reactions.[20]

ABO and Hemolytic Reactions to Platelets

Whenever possible, platelet units are assigned so as to match the donor plasma with recipient RBC type. For example, a type A patient would ordinarily receive type A or AB platelets, which do not contain anti-A antibody. However, when platelet inventories are constrained, it is common for blood banks to issue ABO-incompatible platelets. For example, a type A patient might receive type O platelets, containing anti-A. The passive transfusion of donor anti-A or anti-B to a patient usually does not cause adverse sequelae. Rarely, however, hemolysis may be observed. Most often, this occurs with units from type O donors, who occasionally have high titer anti-A, anti-B, or anti-A,B antibody. In a typical type O adult, the titer of circulating anti-A is on the order of 128 to 256. However, some donors have anti-A titers of 10,000 or higher. Recipients of products from donors with high-titer anti-A (and less frequently, anti-B) rarely do have clinically apparent hemolysis, and a small number of fatalities have been reported. This is considered to be a low-risk event, but it may be on the rise in the United States because of the increased number of single-donor apheresis platelet units used. One strategy to deal with this issue is to measure the anti-A/B titer on all platelet donors; components exceeding a threshold titer are assigned to type-specific recipients. An alternative strategy is to reduce the load of plasma in a platelet unit before transfusing the unit to a non–ABO-identical recipient, either by washing or concentrating the unit, or by using a PAS unit (earlier.)

Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury (TRALI) is an acute respiratory distress syndrome associated with the transfusion of any plasma-containing blood component, including platelets.[21] Most if not all cases of TRALI appear to be precipitated by the passive transfusion of donor anti-HLA or (less commonly) antineutrophil antibody. It is believed that products containing higher volumes of plasma such as fresh-frozen plasma (FFP) and apheresis platelets carry a higher risk of TRALI. Approximately one-third of female blood donors have circulating anti-HLA antibody because of prior sensitization during pregnancy. To help mitigate against the risk of TRALI, many countries, including the United States, now produce FFP from the blood of male donors only. Although this strategy has been relatively easy to apply to FFP production, female platelet donors are still needed to ensure an adequate platelet supply. A variety of strategies are being implemented to screen female platelet donors for anti-HLA antibody and to defer women who are antibody-positive.

D Sensitization

The Rh(D) antigen is the most immunogenic RBC protein antigen. More than 80% of individuals who are D-negative will form anti-D after a single D-positive RBC transfusion. Anti-D is associated with both hemolytic transfusion reactions and hemolytic disease of the fetus and newborn. For this reason, it is standard practice to provide D-negative individuals exclusively with D-negative RBC units. Platelet units contain a small number of contaminating RBCs. In the case of whole blood-derived platelet concentrates, approximately 0.3 to 0.5 mL RBCs may be present. In contrast, current apheresis platelets contain far fewer RBCs (≈0.0002 to 0.0007 mL per unit). When possible, D-negative platelet units are given to D-negative recipients. However, inventory constraints often force blood banks to issue D-positive platelet products to D-negative recipients. Transfusion of such units is associated with a low but nonzero risk of sensitization and formation of anti-D. D sensitization can be prevented by administering Rh immune globulin (RhIG), as is done to prevent fetomaternal Rh sensitization in D-negative mothers of D-positive children. The risk of sensitization is very low among D-negative immunocompromised patients transfused with D-positive platelets (e.g., HSCT patients).[22] In this setting, the value of RhIG prophylaxis appears to be low.

PLATELET REFRACTORINESS

Causes of Refractoriness to Platelet Transfusion

Platelet refractoriness is defined as an inappropriately low platelet increment after repeated platelet transfusions. It can be caused by nonimmune or immune factors (Table 113.1). The most commonly reported nonimmune causes of platelet refractoriness include fever, sepsis, bleeding, splenomegaly, and disseminated intravascular coagulation. In a small subset of cases, platelet refractoriness is immune-mediated. Platelets express HLA class I antigens, ABO antigens, and several platelet-specific antigens. Any of these molecules may potentially serve as an immune stimulus in a transfusion recipient. Antibodies directed against HLA molecules are responsible for most cases of immune-mediated platelet refractoriness, whereas antibodies to the human platelet antigens (anti-HPA) are less frequently implicated.

Diagnosis of Platelet Refractoriness

Because fewer than half of all platelet-refractory patients have demonstrable anti-HLA or antiplatelet antibodies, evaluation of both an immediate response to platelet transfusion and an 18- to 24-hour posttransfusion platelet survival is needed to help establish the cause of platelet refractoriness. Platelet counts obtained from 10 minutes to 1 hour after transfusion that repeatedly fail to demonstrate a corrected count increment of more than 5000/μL usually indicate immune-mediated platelet refractoriness. If the 10-minute to 1-hour posttransfusion platelet count shows a reasonable increment but the platelet count decreases to baseline by 18 to 24 hours, a nonimmune mechanism of refractoriness may be presumed (see Table 113.1). In cases of suspected immune-mediated refractoriness, HLA antibody screening (panel reactive antibody [PRA]) provides valuable supporting evidence that allosensitization has occurred. A patient with a PRA greater than 70% may be considered to be “severely immunized” and a good candidate for HLA-matched platelets (later).

Drug-dependent antibodies	

HLA, Human leukocyte antigen; *HPA*, human platelet antigen.

Detection of Anti-Human Leukocyte Antigen Antibodies

Most commonly, HLA antibodies are identified using flow cytometric detection of antibody binding to beads coated with purified HLA antigens. The flow cytometry-based methodology has significantly improved sensitivity over lymphocytotoxicity assays (LCA), and, similar to solid-phase assays, it can detect both complement-fixing and non–complement-fixing antibodies.

Detection of Antiplatelet Antibodies

The most commonly used methods for detection of anti-HPA antibodies are solid-phase assays using purified platelet antigens for detection of antibody specificity. However, testing for anti-HPA antibodies is not typically performed in the work-up of platelet-refractory patients, mainly because the importance of these antibodies in causing clinical refractoriness is not well established.

Prevention of Alloimmunization

Although they express HLA class I antigens, platelets themselves are fairly weak immunogens. It has been shown that contaminating leukocytes in platelet products are primarily responsible for stimulating HLA antibody formation in platelet transfusion recipients. Thus removing WBCs from blood products (leukoreduction) is an essential means of preventing alloimmunization and subsequent platelet refractoriness. The definitive study showing this was the Trial to Reduce Alloimmunization to Platelets (TRAP)[23] which compared alloimmunization rates in 530 newly diagnosed patients with acute myeloid leukemia randomized to receive unmodified, pooled platelet concentrates (control); filtered, pooled platelet concentrates (F-PCs); filtered, single-donor apheresis platelets (F-APs); or UV-B-irradiated pooled platelet concentrates (UVB-PCs). Anti-HLA antibodies were detected in 45% of control participants compared with 17% to 21% of patients receiving modified platelets. A total of 13% of control group patients became platelet refractory versus only 3% in the F-PC group, 4% in the F-AP group, and 5% in the UVB-PC group.

Management of Platelet-Refractory Patients

When platelet refractoriness has been demonstrated, several strategies may facilitate achieving therapeutic platelet increments in vivo (Table 113.2). A trial of ABO-matched, fresh (1 to 2 days old) platelets may be helpful. In cases of immune-mediated refractoriness, a trial of HLA-matched platelets, antigen-negative platelets, or crossmatched platelets should be considered. The basic principles for selection of HLA-matched platelets are outlined in Table 113.3. In most cases, alloimmune refractory patients will show some degree of response to HLA-matched platelets. Because of the high degree of polymorphism of the HLA loci, it is often not possible to find perfect HLA-A and HLA-B locus matches, leading to the use of platelets mismatched at one or more loci (Table 113.4). In general, transfusion of grade A- or BU-matched platelets can result in an increase in platelet count that is superior to platelet increment obtained using either crossmatched

TABLE 113.2 Management of the Platelet-Refractory Patient

Obtain 10-min to 1-h posttransfusion platelet count on two occasions

If there is an appropriate increment in platelet count after a single platelet transfusion, continue to transfuse random platelets and treat nonimmune factors associated with decreased platelet survival such as sepsis and DIC, discontinue offending drugs, and so on

If the 10-min to 1-h posttransfusion platelet counts demonstrate no platelet increment (or only a marginal increment), obtain the patient's HLA type and screen the patient for the presence of anti-HLA antibodies (panel reactive antibody test)

While awaiting HLA antigen typing and antibody screening results, consider transfusion of "fresh" (<3 days old) ABO-matched platelets

If PRA shows less than 20% reactivity, continue with "fresh" ABO-matched random platelets

If PRA shows more than 20% reactivity, obtain anti-HLA antibody specificity. Use the recipient's HLA typing information to locate grade A– or grade B–matched platelet units for transfusion. Avoid transfusion of platelets containing antigens against which the recipient has antibodies. Consider recruiting recipient's family for platelet donation

Transfusion of crossmatch-compatible platelets is an option if there is a poor response to grade A– or grade B–matched platelets or if the recipient has antibodies to platelet-specific antigens

All HLA-matched or crossmatched platelet units must be irradiated before transfusion to prevent transfusion-associated GVHD

DIC, Disseminated intravascular coagulation; *GVHD*, graft-versus-host disease; HLA, human leukocyte antigen; *PRA*, panel reactive antibody.

TABLE 113.3 Traditional Platelet Selection Guidelines for Refractoriness Caused by Alloimmunization

ABO antigens are expressed on platelets. Consider transfusion of ABO-matched platelets while awaiting the recipient's HLA type and antibody specificity

Platelet matching for the recipient's HLA-A and HLA-B antigens is important

Platelet matching for the recipient's HLA-C antigens is not essential

Determine the antigen specificity of recipient's antiplatelet antibodies and try to transfuse antigen negative platelets

Some HLA antigens may be weakly expressed on platelets. Consider giving platelets mismatched for those antigens (e.g., HLA-B12 and its splits B44 and B45)

If HLA-matched platelets are unavailable, consider transfusion of platelets mismatched for HLA antigens that are serologically cross-reactive with the recipient's HLA antigens

If platelets mismatched for serologically cross-reactive antigens are not effective, matching for HLA-associated antigen systems such as Bw4/Bw6 may be helpful

HLA, Human leukocyte antigen.

platelets or platelets with different degrees of HLA mismatching (BX, C, or D). An additional step that may help in finding compatible platelets is flow cytometric detection of anti-HLA antibody specificity using single HLA antigen-coated beads. This information can be used to find donors who may be HLA-mismatched with the recipient but whose platelets lack the antigens to which the patient has specific antibodies. Furthermore, family members may be considered as platelet donors in addition to the available pool of HLA-matched volunteer donors. As an alternative to HLA antigen matching, patients may benefit from receiving donor platelets that are crossmatch-compatible with the patient's serum. The major benefit of crossmatching is a potentially larger pool of donors who would have been excluded by strict HLA antigen matching. In addition, platelet crossmatching may be helpful in cases of refractoriness caused by antibodies directed against platelet-specific antigens.[24]

The most challenging cases are the rare instances involving immune-refractory patients who are actively bleeding and HLA-matched platelets or crossmatched platelets are either ineffective or unavailable. In such cases, patients are typically transfused with repeated doses of random HLA-incompatible platelets during hemorrhagic episodes. The efficacy of this practice is unclear.

TABLE 113.4 Grades of Human Leukocyte Antigen–Matched Platelets

Match Grade	Description
A	4-antigen match (donor and recipient match at both HLA-A and HLA-B loci)
B1U	1 antigen unknown or blank (e.g., donor is: A2, –; B5, 27)
B1X	1 cross-reactive group[a]
B2UX	1 antigen blank and 1 cross-reactive[a]
C	1 mismatched antigen present
D	≥2 mismatched antigens present
R	Random

[a] The clusters of human leukocyte antigen (HLA) that share antigenic epitopes can be classified into cross-reactive antigen groups. Antibodies recognizing one HLA molecule within the group cross-react with other members of the same group.

CHAPTER 114

HUMAN LEUKOCYTE ANTIGEN AND HUMAN NEUTROPHIL ANTIGEN SYSTEMS

Ena Wang, Sharon Adams, David F. Stroncek, and Francesco M. Marincola

This chapter reviews human leukocyte antigen (HLA) and human neutrophil antigen (HNA) systems. A general background of the structure, function, and nomenclature of both systems and their relevance in clinical hematology is presented. Analysis of HLA gene products is applied in clinical settings (1) to select compatible donor-recipient pairs for transplantation, (2) to select HLA-compatible single-donor platelet products for thrombocytopenic patients refractory to standard transfusion of random pooled platelets, (3) to screen for genetic factors that may contribute to the prevalence of diseases, and (4) for forensic purposes in which the identity of individuals may contribute to solving legal disputes or criminal investigations. In addition, we discuss new applications that have broadened the relevance of HLA in the area of immune pathology. HLA phenotypes determine the suitability of patients for epitope-specific immunization. Tetrameric HLA/epitope complexes (tHLA) allow enumeration of antigen-specific T-cell responses. Furthermore, molecular identification of T-cell epitopes associated with distinct diseases and characterization of the communication between immune effector cells through HLA-HLA ligand interactions extend the relevance of HLA to biologic fields. These biologic fields encompass natural killer (NK) and cytotoxic T-cell function, antigen recognition in the context of infection, autoimmunity, the graft-versus-neoplasia (GVN) effect, and autologous cancer rejection. Finally, the recognition that polymorphism extends to other protein families relevant to immune pathology including cytokines, their receptors, and killer cell–inhibitory receptors has broadened the significance of immunogenetics beyond HLA. Thus, this chapter emphasizes the importance of viewing human pathologic conditions through the kaleidoscopic complexity of human polymorphism.

THE GENETICS, STRUCTURE, AND FUNCTION OF HUMAN LEUKOCYTE ANTIGEN MOLECULES

HLAs comprise a family of genes clustered in the short arm of chromosome 6 as the human version of the major histocompatibility complex (MHC), initially identified in mice as responsible for graft rejection between genetically unrelated strains (transplantation antigens).[1] Credit for the description of the human MHC goes to three individuals. In 1952, Jean Dausset observed that the serum of individuals who had received several transfusions contained hemagglutinins specific for donors' leukocytes. In 1958, Rose Payne noted that the only requirement for the development of hemagglutinins against leukocytes was a history of previous transfusion or pregnancy and concluded that these antibodies were directed against antigens on the surface of circulating leukocytes. This conclusion was concomitantly and independently confirmed by Jon van Rood, who observed that multiple pregnancies immunize mothers against leukocytes leaked from the fetus into the mother's circulation. Based on these discoveries, the term *human leukocyte antigen* was subsequently adopted.[2] It should be clarified, however, that this historical name is misleading. HLA molecule expression is not limited to leukocytes nor do they display, in natural conditions, antigenic behavior. In fact, several are expressed by most somatic cells, and, rather than being antigens, they chaperone protein bioproducts to the cell surface for recognition by T cells. There is, however, some substance to the name, because HLAs, by virtue of being densely packed on the cell surface, are exposed to recognition in a foreign environment, such as allotransplantation or xenoinfusion performed to induce anti-HLA antibodies as diagnostic reagents.

ORGANIZATION OF THE HUMAN LEUKOCYTE ANTIGEN GENES

HLA genes constitute a string of coding sequences that regulate the expression of molecules with similar but not identical function. Residing in a region that spans approximately 4000 kilobases of the short arm of chromosome 6 (Fig. 114.1),[3] HLA contains several genes and pseudogenes characterized by sequence homology and functional similarity. Of them, 47 are officially recognized by the World Health Organization (WHO) Nomenclature Committee[4] and include classic HLA class I and class II genes associated with antigen processing, such as PSMB8 and PSMB9 (proteasomal units) or TAP1 and TAP2 associated with peptide transport. Both HLA and HLA-associated genes can be physically grouped into three subregions according to chromosomal location. In the centromeric to telomeric direction, the first is HLA class II region comprising the α-and β-chains of HLA-DR, -DQ, -DP, -DM, and -DO as well as TAP and PSMB. Sandwiched between the class II and class I region, the class III region encodes for functionally unrelated genes such as complement components, heat shock proteins, and the tumor necrosis factor. The reason for their genetic link to the HLA complex is unknown, but their immunologic function seems more than coincidental. The class I region is most telomeric and includes HLA-A, -B, and -C loci; the nonclassic HLA-E, -F, and -G loci; and several pseudogenes.

General terminology separates HLA genes into classic and nonclassic. Classic HLA genes have been well characterized and are clearly associated with the presentation of antigens to immune cells. They are further subdivided into class I (HLA-A, -B, -C) and class II (HLA-DR, -DQ, and -DP). In general, HLA class I and II genes have very similar structure and function.[5,6] They contain six to eight exons coding for functionally distinct domains (Fig. 114.2). The first exon encodes a leader sequence; the following exons (exons 2 to 4) are highly polymorphic and encode extracellular domains responsible for peptide binding and T cell–antigen receptor (TCR) engagement. Because they are exposed on the cell surface, these domains are also responsible for alloreactivity. The last exons encode a conserved transmembrane and small intracellular domains whose function is unclear.

Only the heavy chain of HLA class I is encoded in the MHC region. Genes encoding HLA-A, -B, and-C contain three exons coding for α_1, α_2, and α_3 extracytoplasmic domains, one transmembrane, and three cytoplasmic domains (Fig. 114.3). The associated class I light chain, β_2-microglobulin, is encoded on chromosome 15.[7] By contrast, the HLA class II molecule is composed of a heterodimer of an α-chain and a β-chain encoded in the MHC region. Although the genetics are different, the protein product is structurally similar to HLA class I, with two helices resulting in the antigen-presenting part of the molecule (Fig. 114.4).

All DR molecules use DRA for α-chains but can use alleles coded by DRB1, DRB3, DRB4, or DRB5 for β-chains. DP, DQ, DM, and DO molecules are the product of DPA1 and DPB1, DQA1 and DQB1, DMA and DMB, and DOA and DOB genes, respectively. The HLA DRB1 locus is expressed in all HLA haplotypes (the set of HLA alleles derived from the same parental chromosome and therefore genetically linked). However, only one other HLA DR locus is present in each individual chromosome. Thus, each haplotype can have either DRB5 (DR1 haplotype); DRB3, -B4, or -B5 loci (DR2 haplotype); DRB4 locus (DR4 and DR7 haplotype); or none (DR8 and DR10 haplotype).[3]

INHERITANCE AND LINKAGE DISEQUILIBRIUM

Because of their proximity within a short chromosomal distance, HLA genes are inherited en bloc from each parent unless a recombinant event occurs. Thus each HLA haplotype behaves as a unit and is transmitted through generations according to mendelian principles. Because there are four possible genotypes (two from each parent), the probability of genotypic identity between two siblings is 25%. Most HLA phenotypically identical siblings are also HLA genotypically identical, because the genetic pool of derivation is restricted to the parents. In 2% of cases, recombinant HLA haplotypes (a set of genes derived partially from two chromosomes through recombination) deviate from this rule.

The occurrence of HLA haplotypes within a population with a frequency higher than expected from the prevalence of individual alleles is called *linkage disequilibrium*. In large populations, gene frequencies achieve equilibrium within a few generations unless selective pressure influences individuals' survival and mating capacity (Hardy-Weinberg principle). In equilibrium, gene prevalence is maintained based solely on its frequency. Thus, assuming that there were 18, 36, and 8 alleles for the HLA-A, -B, and -C loci, respectively (number of alleles known when this example was described[2]), theoretically, 18 × 36 × 8=5184 HLA class I allelic combinations or haplotypes would be possible. Adding HLA class II genes to the calculation yields an astronomical number, making the identification of two HLA-matched individuals unlikely. However, individual alleles occur with different frequency, and an allele that occurs with high frequency is predominant in a given population, such as HLA-A2 in persons of European ancestry and A24 or A11 in Asians.[8] Because predominant alleles come with the related haplotype, most theoretical permutations never occur, and the chances of identifying matched individuals are much higher than theoretically possible.

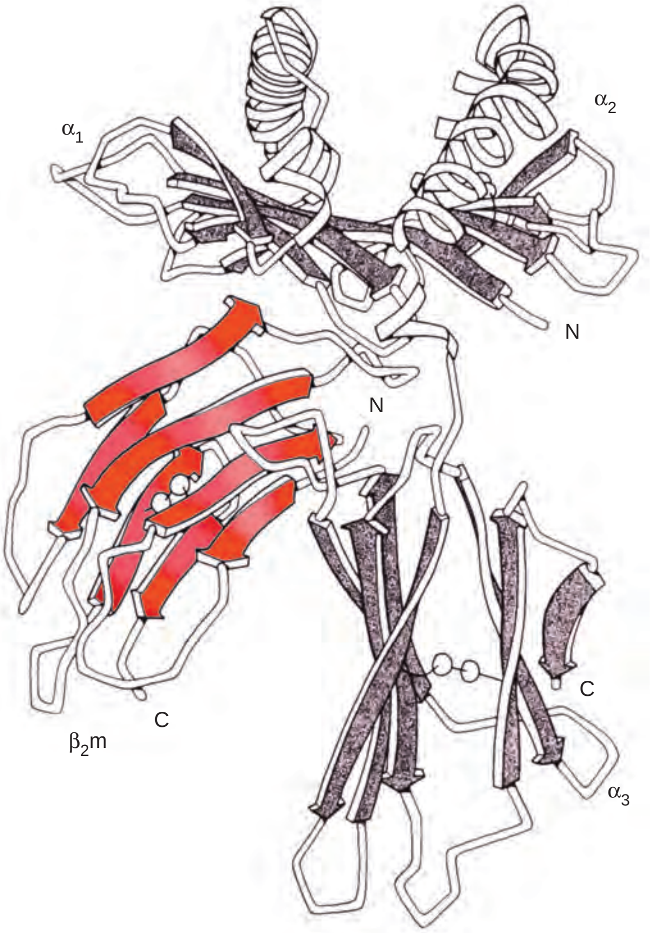

Figure 114.3 THREE-DIMENSIONAL CONFIGURATION OF HLA-A2, MODELED FROM X-RAY CRYSTALLOGRAPHIC STUDIES. *HLA*, Human leukocyte antigen. *(From Bjorkman PJ, Saper MA, Samraoui B, et al. Structure of the human class I histocompatibility antigen, HLA-A2. Nature. 329:506, 1987.)*

STRUCTURE OF THE HUMAN LEUKOCYTE ANTIGEN CLASS I AND II

The structure of HLA molecules and their relationship with their natural ligand, the TCR, has been well characterized by crystallography.[9–11] HLA molecules are heterodimer glycoproteins belonging to the immunoglobulin superfamily with common features (see Fig. 114.4). This includes two α-helical domains protruding toward the extracellular milieu. Between them lies a flat surface formed by β-sheet structures that contributes to the formation of a groove accommodating peptides generated from intracellular (HLA class I) or extracellular proteins (HLA class II) (Fig. 114.5). The helices/peptide complex is exposed for TCR recognition. Because HLA polymorphism is clustered within the α-helixes and β-sheets domains, peptides display variable affinity for distinct HLA alleles.[12,13] It has been proposed that a given peptide can bind to closely related alleles, and HLA superfamilies with similar binding characteristics have been described.[14–16] However, peptide binding to related but distinct HLA alleles is associated with conformational dissimilarity caused by differential interaction with variant residues in the binding groove.[17] The TCR interaction with HLA required for productive engagement spans a surface including the peptide and portions of the α- and β-helix.[11,18–20] This double requirement of interaction between the TCR and the HLA/peptide complex represents the structural basis for HLA restriction. Degenerate and promiscuous TCR recognition of peptides presented by distinct HLA alleles within the same superfamily has also been described.[21] Although this concept holds in general, several exceptions can be expected because single amino acid variants in the HLA molecule may disallow binding of a peptide[22] or may not be permissive to TCR engagement.[23,24]

The binding affinity of a given peptide for an HLA allele can be predicted through algorithms that compile available information to identify amino acid residues that fit distinct pockets of the HLA groove.[13,25] Several algorithms implement this information with experimental testing based on the refolding capability of HLA heavy chains exposed to known peptide sequences in the presence of β_2-microglobulin and/or their dissociation rates (see www.bimas.dcrt.nih.gov or www.uni-tuebingen.de/uni/kxi). This is based on the principle that the affinity of a peptide for a given HLA promotes the stability of the noncovalent assembly of heavy chain with β_2-microglobulin.[13,26] Finally, peptide binding can be shown by direct elutriation from purified HLA heavy chains.[12,27]

Beyond the interactive component of the HLA molecule with the TCR, other domains act as coreceptors for the TCR. CD8$^+$ cytotoxic T cells bind to the α_3-domain of HLA class I through CD8, whereas CD4$^+$ T cells interact with HLA class II–specific domains. Although the coreceptor-TCR interaction is not an absolute requirement in most cases, it determines HLA class I or II restriction of individual T cells.[28] Specific to HLA class I is the assembly with β_2-microglobulin on stabilization in the presence of high-affinity peptides derived from the cleavage of intracellular proteins (endogenous pathway of antigen presentation).[29] Most peptides derive from degradation of self-protein in the cytosol by proteasomes (PSMB) and other proteases.[30] Soluble peptides (9 to 10 amino acids long) are then chaperoned into the endosomal compartment by transporter molecules associated with antigen processing (TAP1 and TAP2). Within this compartment, they bind to heavy chains according to each individual's HLA phenotype. The binding and stability of the HLA-peptide complex depends on the affinity of each peptide for a particular allele. If the stability is sufficient, the peptide-loaded HLA migrates to the cell surface. Intracellular pathogens produce proteins that are also degraded by proteasomes into peptides that compete with self-peptides for binding to HLA class I molecules. Thus, the function of the endogenous pathway of antigen presentation is to provide information to the extracellular compartment of intracellular events. In physiologic conditions, only self-peptides are presented, and therefore minimal interactions occur with circulating T cells. During infection, pathogen-derived peptides signal cellular infection to T cells, whereas antibodies that cannot cross the cell membrane remain insensitive to intracellular pathogens. Several pathogens, such as cytomegalovirus, can interfere with this process as well as with reduction of HLA/peptide density on the cell surface and, consequently, diminished T-cell recognition.[31,32] This escape mechanism can be counteracted by the host through increased susceptibility of virally infected cells to NK cell-mediated cytolysis.[33] Reciprocally, viruses can evade NK cells and escape recognition by modulating HLA expression.[34–36]

HLA class II molecules bind to longer peptides derived from the metabolism of molecules endocytosed from the extracellular compartment (exogenous pathway of antigen presentation).[29] This is a specialized process used by professional antigen-presenting cells, such as macrophages and dendritic cells. HLA class II molecules are assembled within the endosomal compartment where they are composed of a heterotrimer. This includes the α- and β-chains plus a short invariant chain that stabilizes the molecule by occupying its groove while chaperoning its migration to the endosomal compartment where exogenous antigen is processed. Upon uptake, the exogenous antigen undergoes limited proteolysis in the membrane-bound acidic endosomal compartment (MHC class II peptide-loading compartment, MIIC). Upon entering the MIIC, the pre-HLA class II complex is degraded, and antigenic peptides are loaded with the help of the nonclassic HLA-DM molecule.[37]

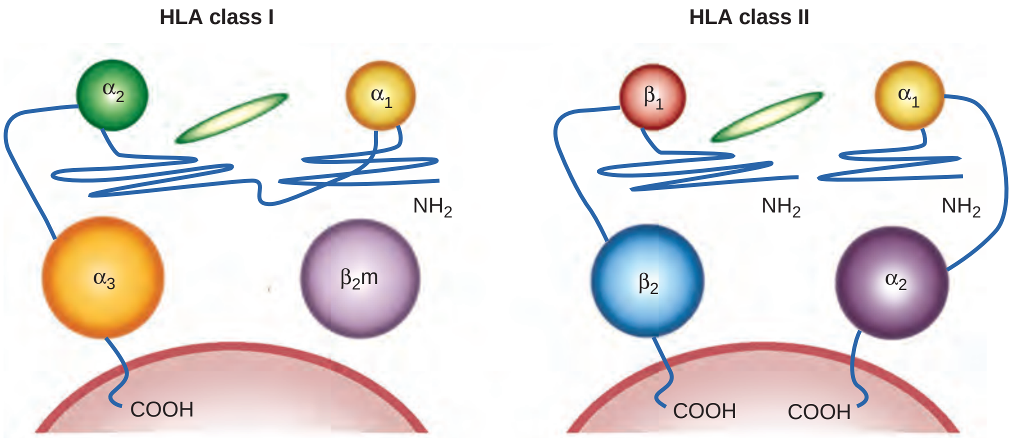

Figure 114.4 SCHEMATIC DIAGRAM OF HUMAN LEUKOCYTE ANTIGEN (HLA) CLASS I AND CLASS II MOLECULES POINTING TO THEIR STRUCTURAL SIMILARITY. In both HLA classes, two immunoglobulin-type domains reside close to the cell membrane (α_3 and β_2m for class I and α_2 and β_2 for class II). The other two domains project toward the extracellular milieu with α-helices (α_1 and α_2 for class I and α_1 and β_1 for class II) and a platform of parallel β-sheets that form a peptide-binding groove.

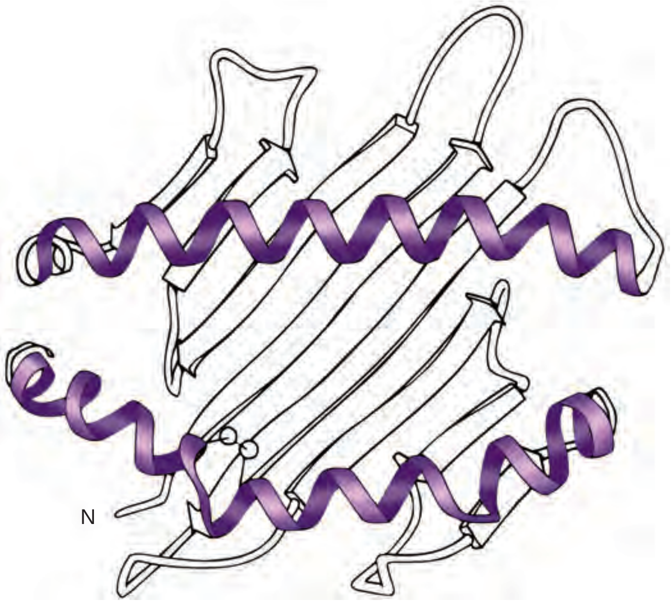

Figure 114.5 SCHEME OF THE PEPTIDE GROOVE OF A HUMAN LEUKOCYTE ANTIGEN (HLA) CLASS I MOLECULE, FORMED BY THE α1 AND α2 DOMAINS AT THE SIDE AND THE β-SHEETS AT THE BOTTOM. The view is looking down on the vertically oriented molecule: the T-cell receptor point of view. *(From Bjorkman PJ, Saper MA, Samraoui B, et al. Structure of the human class I histocompatibility antigen, HLA-A2. Nature. 1987;329:506.)*

EXPRESSION OF HUMAN LEUKOCYTE ANTIGEN MOLECULES

There are genetic and structural differences between the two classes of HLA alleles. The most striking difference is functional, because HLA class I molecules are expressed by most nucleated cells with the exception of germinal cells, whereas HLA class II molecules are expressed mainly by specialized antigen-presenting cells.[38,39] HLA class I molecules are also expressed by platelets.[40] They are responsible for refractoriness after multiple transfusions[41–44] and sufficiently, though minimally, expressed by reticulocytes to be targets of alloantibodies during hemolytic transfusion reactions.[45] HLA class II proteins are expressed constitutively by cells associated with the initiation of the immune response, such as monocytes, macrophages, and B cells,[46] or by immune cells activated by cytokines during inflammation. Thus HLA class I molecules instruct the host about the condition of individual cells as potential targets for CD8$^+$ cytotoxic T cells responsible for clearing the organisms of altered cells. HLA class II molecules initiate immune responses by taking up pathogen components and presenting them to CD4$^+$ helper T cells, which can in turn initiate humoral and facilitate cellular immune responses.

Expression of HLA alleles is sensitive to environmental conditions and can be modulated by cytokines among which interferons play a major role.[47] This is particularly important for HLA-B and HLA-C normally expressed at a lower density than HLA-A but more sensitive to cytokine induction.[48,49] In addition, HLA class II molecules can be expressed by most cells following cytokine stimulation.[50,51] Thus the ability of cells to present antigens in association with HLA is strongly influenced by the surrounding environment. This might explain why chronic inflammation induced by alloreactions during graft-versus-host disease (GVHD) may facilitate the presentation of tumor-specific antigens by tumor cells with consequent development of the GVN effect. In addition, it might explain how systemic administration of proinflammatory cytokines such as interleukin-2 may stimulate immune responses by increasing the antigen-presenting ability of cells within the tumor microenvironment.[52]

HUMAN LEUKOCYTE ANTIGEN POLYMORPHISM AND ITS CLINICAL SIGNIFICANCE

A striking characteristic of the HLA system is its extreme polymorphism.[53] By chance, most individuals are heterozygote and therefore carry two different alleles for each HLA gene that, being codominant, are equally expressed on the cell surface. Because everybody carries three HLA class I (-A,-B, and -C) and three HLA class II (-DR, -DQ, and -DP) genes, most individuals (with the exception of homozygotes) express six different HLA class I and six different HLA class II molecules on the surface of their cells. This has important functional implications, because HLA polymorphism is clustered in domains of the HLA molecule associated peptide binding and interaction with the TCR. Thus, most individuals have a broad repertoire of molecules capable of presenting different pathogen components to immune cells. Therefore, it is believed that HLA polymorphism improves the chances of a given species of surviving infection.[54] This paradigm is difficult to demonstrate in human pathologic conditions in which the natural history of infectious diseases rarely correlates with HLA phenotype. An exception is the strong association between

HLA-B*5701 and lack of progression to acquired immunodeficiency syndrome of individuals infected with human immunodeficiency virus (HIV).[55] Associations have been observed between HLA phenotype and predisposition for nasopharyngeal carcinoma.[56,57] This is of particular interest because nasopharyngeal carcinoma is a virally induced cancer against which T cells can mediate immune surveillance. HLA associations have also been described with less consistency for other virally driven tumors, such as cervical carcinoma,[58] or immunogenic tumors, such as melanoma.[59,60]

The difficulty in demonstrating conclusive associations between infectious disease and HLA in humans could be caused by the successful implementation of antigen presentation through a broad repertoire of HLA genes, which could compensate for each other in limitations in antigen presentation. Chickens carry a single MHC locus, and their susceptibility to infection appears to be clearly related to MHC. For instance, Kaufman et al.[54] have shown that chickens carrying a particular Bf (the only MHC class I gene in chickens) allele are fully protected from Rous virus-induced sarcomas because this allele (B-f12) can bind several antigenic peptides from its proteins. On the contrary, chickens homozygous for B-f4 are killed by the same infection because this allele cannot bind peptides from sarcoma virus proteins.[54]

HLA polymorphism is the basis of alloimmunization because most individuals are likely to have different HLA molecules on the surface of their cells. Hundreds of HLA alleles have been identified through high-resolution typing, making the chances of two individuals having identical HLA phenotypes extremely low. Thus partial mismatches are commonly accepted in transplantation cases, which are at the root of hyperacute, acute, and chronic rejections. Hyperacute rejection is caused by preformed antibodies against donor HLA alleles in patients presensitized by multiple transfusions.[61] Acute and chronic rejection result from a combination of humoral and cellular immune reactivity toward HLA alleles of the donor.[62,63] In addition to allosensitization, HLA alleles can mediate GVHD, whereby hematopoietic cells derived from the grafted tissue recognize and reject the host tissues. They do this by identifying polymorphisms of intracellular proteins of the host (minor histocompatibility antigens [mHags]) presented in association with donor-recipient matched HLA alleles.

NONCLASSIC MAJOR HISTOCOMPATIBILITY COMPLEX AND MAJOR HISTOCOMPATIBILITY COMPLEX CLASS I CHAIN-RELATED MOLECULES

Besides the three ubiquitously expressed highly polymorphic classic HLA class I molecules, humans encode three relatively conserved nonclassic, selectively expressed (HLA-E, -F, and -G) MHC class I genes (also known as MHC-Ib). These evolved at different rates in primates reflecting differential involvement in the modulation of immune responses.[4,64,65] In addition, these molecules are characterized by unique patterns of transcription, protein structure, and immunologic function.[66]

The MHC class I–related chain genes (MICA and MICB) are located within the MHC region and are characterized by high polymorphism (more than 50 alleles so far identified).[67] The molecules encoded by these genes do not appear to bind peptides or associate with β_2-microglobulin. Their polymorphic variants are not concentrated around the peptide-binding groove, yet they seem to have functional significance, because most mutations are nonsynonymous, suggesting selective pressure as a driving force. Their tissue distribution is restricted to epithelial and endothelial cells and fibroblasts. It appears that MIC genes modulate the function of NK and CD8$^+$ T cells by binding the NKG2D stimulating receptor.[68] Also, MIC genes have been implicated in transplant rejection because alloantibodies against them are often found in transplant recipients that may exert complement-mediated cytotoxicity against endothelial cells from the graft.

Other unusual MHC-like molecules are present in the genome and have disparate functions, including presentation of lipid antigens (CD1), transport of immunoglobulins (Fc receptor), and regulation of iron metabolism (hemochromatosis gene product).[69] Contrary to classic MHC class I genes that are constitutively expressed, nonclassic MHC and MIC gene expression depends on stimulation by proinflammatory cytokines.[70] In addition, two nonclassic MHC class II proteins (HLA-DM and HLA-DO) have been described that function as mediators of peptide exchange by stabilizing empty MHC class II molecules.[37] Finally, it is possible that several nonclassic MHC molecules whose function is to present peptides to lymphocytes may be present throughout the genome. Because of their limited polymorphism, however, these genes may have evolved to serve specialized presentation functions.[71]

Characterized by low polymorphism, the regulation of HLA-G expression follows a nonclassic behavior. Aberrant cytokine-responsive regulatory sequences[72–74] may be responsible for its predominant expression by trophoblasts that do not express other HLA proteins.[75] It may also account for its low levels in a variety of human tissues.[76] Lack of responsiveness to common immunostimulatory pathways (NF-κB, interferon-γ, or CIITA) is most pronounced in HLA-G cells and is shared by other nonclassic MHC such as HLA-E.[77] Also, HLA-G is expressed in a variety of cancers.[72] It is hard to know what the relevance of HLA-G expression is because it can occur in various membrane-bound or soluble isoforms with distinct functional characteristics.[72] Functional isoforms that include the α-1 and α-2 domains bind and present peptides from cytoplasmic proteins.[78] Because of the minimal polymorphism, however, the repertoire of peptides presented is likely to be limited, suggesting that peptide binding is necessary to stabilize the molecule rather than being involved in antigen presentation.

Functionally, HLA-G is thought to modulate the function of NK cells through interactions with their inhibitory receptors.[79] In addition, the HLA-G leader sequence contains a peptide that can bind and stabilize the expression of HLA-E, which in turn inhibits NK cells.[80] Because the HLA-G–derived leader peptide has the strongest affinity for HLA-E (among all HLA class I molecules), it is likely that HLA-G is a powerful direct and indirect inhibitor of NK cells, reducing the risk for cardiac rejection[81] or inducing immune escape of cancer cells.[72] Although much has been published about the immunoregulatory role of HLA-G, its true function remains mysterious, principally because of discordant findings reported by various groups.[74] With the goal of achieving consensus, a workshop was recently organized to standardize methods of analysis of HLA-G.[66]

HLA-E is minimally polymorphic,[4] binds hydrophobic peptides from other HLA class I leader sequences, and interacts with CD94/NKG2 lectin-like receptors present predominately on NK and partially on CD8$^+$ T cells.[82–85] The peptide binding is highly specific and stabilizes the HLA-E protein, allowing its migration to the cell surface. Thus surface density of HLA-E is an indirect reflection of the number of HLA class I alleles expressed by a cell.[86] The interaction of HLA-E with CD94/NKG2 protects HLA-E–expressing cells from killing. Cells damaged by viral infection or neoplastic degeneration may lose HLA class I expression. As a backup mechanism of protection, reduced HLA class I expression results in decreased expression of HLA-E, leading to vulnerability to NK cells.[87] Some viruses express mimic peptides that bind and stabilize HLA-E so that, although classic MHC molecules are downregulated, HLA-E expression is maintained, allowing the pathogen to simultaneously escape CD8$^+$ T- and NK-cell killing.[88]

The function of HLA-F remains enigmatic. Its transcriptional regulation is closest to classic HLA molecules in that it can be induced by NF-κB, interferon regulatory factor-1, and class II trans-activator.[89] However, contrary to classic HLA molecules, HLA-F is predominantly empty, mostly intracellular, with a restricted pattern of expression.[90] Its tissue distribution appears to be limited to B cells, and therefore it is mostly found in lymphatic organs.[90] Structural studies suggest that HLA-F is a peptide-binding molecule and may reach the cell surface under favorable conditions when a suitable peptide is present.[91] Once on the cell surface, HLA-F may interact with the effector-cell receptors IL-T2 and IL-T4, as suggested by HLA-F tetrameric complexes–binding studies.[91] Thus it is possible that in specific yet unknown conditions, HLA-F may modulate the function of immune effector cells similarly to HLA-E and HLA-G.

NON-HUMAN LEUKOCYTE ANTIGEN POLYMORPHISM AND ITS CLINICAL SIGNIFICANCE

Although this chapter is dedicated to HLA, it would be incomplete without mentioning the increasingly recognized polymorphisms of other immune modulators. The significance of non-HLA polymorphism is evidenced by the development of GVHD in the presence of HLA identical matching among relatives. As recently summarized,[92] three general areas of polymorphism are being investigated: NK cell–receptor genes, minor histocompatibility antigens, and cytokines. Over the last decade, much progress has been made in identifying the mechanisms of action of NK cells. A major breakthrough was made in the discovery of HLA class I-specific inhibitory receptors and in the role that they play in the regulation of NK function with consequent effects on the eradication of hematologic malignancies, prevention of graft rejection, or induction of GVHD.[93] NK cells recognize HLA molecules via killer immunoglobulin-like receptors (KIRs). The regulation of NK cell function by KIRs is further discussed in Chapter 12. KIRs are glycoproteins encoded by at least 17 different genes located on chromosome 19q13.4.[94] All human KIR genes derive from a gene encoding three immunoglobulin (Ig)-like domains (D0, D1, and D2) and a long cytoplasmic tail. However, the KIRs genes are diverse and may encode either two or three Ig-like domains and either a long or short cytoplasmic tail (Table 114.1). The long cytoplasmic tails contain one or two immunoreceptor tyrosine-based inhibition motifs.[95] Although KIR molecules with long cytoplasmic tails inhibit NK cytotoxicity, those with short tails do not. The names given to KIR genes are based on the molecule that they encode. The first digit corresponds to the number of Ig-like domains in the molecule and a *D* denotes domain. The D is followed by either an *L* for long cytoplasmic tail or *S* for short cytoplasmic tail or *p* for a pseudogene. The last digit indicates the number of the KIR gene.[96]

Expression of KIR in individual NK cells is complex because NK cells may express several members of the KIR family. The number of KIR genes in each haplotype varies among individuals. The most common haplotype is known as group A, which is made up of six genes (2DL1, 2DL2 or 2DL3, 3DL1, 3DL2, 2DS4, and 2DL4). Various KIR genes can recognize different HLA-A, HLA-B, and HLA-C molecules. HLA-C antigens can be divided into two groups based on polymorphisms at amino acid positions 77 and 80 of their class I heavy chains. One group has asparagine (Asn) at position 77 and lysine (Lys) at 80, and the other has serine (Ser) at 77 and Asn at 80. Some KIRs recognize HLA-C antigens with Asn 77 and Lys 80, whereas other KIRs recognize HLA-C antigens with Ser 77 and Lys 80. The polymorphism at position 80 is most important. Another group of KIR reacts with HLA-B antigens that carry specific combinations of amino acids at positions 77 and 83 of the heavy chain that forms HLA-Bw4. Because a single KIR can interact with multiple HLA class I alleles, KIR recognition of HLA class I molecules is degenerate. Another NK inhibitory receptor (CD94-NKG2A) recognizes the nonclassical HLA-E molecule. In addition, each of the KIR genes is extensively polymorphic.

Because the genes for KIR, HLA, and CD94-NKG2A are located in separate chromosomes, they segregate independently, and consequently individuals can carry genes for KIR for which there is no correspondent HLA ligand.[97] Because HLA-E is expressed in all individuals, NK cells that bear the CD94-NKG2A receptor are not alloreactive. Because the specificity of KIR for their ligands is broad and each individual carries several KIRs, it is likely that in most cases all NK cells of a given person express at least one KIR that is specific for a self-HLA class I allele. Thus in autologous settings, NK cells kill only aberrant cells that have lost HLA class I expression. By contrast, NK cells can kill allogeneic cells that do not express HLA class I alleles recognized by their KIR. Thus, by knowing the KIR repertoire of a given transplant recipient and the HLA type of the donor, it would theoretically be possible to predict the likelihood of an NK-mediated alloreaction. Importantly, it appears that alloreactive NK cells undergo proliferation on exposure to the stimulatory cells and therefore can preferentially expand in the presence of allogeneic tissue. NK cells also express activating receptors that are responsible for their lytic activity. Although the identity of the ligands for these receptors has not been identified, it is possible that they are expressed primarily by activated or proliferating cells. It is therefore possible that during the inflammatory process induced in allogeneic conditions, normal cells can become activated by cytokines and express ligands, which are responsible for NK activation in the absence of HLA class I molecules reactive with the inhibitory receptors.[93] The relevance of KIR in transplantation has been well studied in the context of haploidentical hematopoietic transplantation. In this case, several combinations are possible: NK cells from the graft express KIRs that do not interact with the donor's HLA (graft-versus-host alloreactivity). It seems that the presence of graft-versus-host reactive NK cells associated with incompatibilities between donor and recipient (especially HLA-C families) has favorable effects on the outcome of acute myeloid leukemia.[98] Alternatively, a good match may be present between graft NK and host HLA as well as between host NK and graft HLA. In such a case, no alloreactivity occurs. Finally, the graft's HLA type may be unsuitable for the host's NK repertoire, and the host's reactivity may lead to graft rejection. Alloreactive grafted NK cells seem to prevent GVHD while inducing GVN.[93]

TABLE 114.1 **HLA Class I Alleles Recognized by Different Killer Immunoglobulin-Like Receptors**

KIR	HLA Class I Allele	Amino Acid Sequence Motif
P58.1 (KIR2DL1)	HLA-C2, -C4, -C5, -C6	Asn 77, Lys 80
P58.2 (KIR2DL2/3)	HLA-C1, -C3, -C7, -C8	Ser 77, Asn 80
P70 (KIR3DL1)	HLA-Bw4 public specificity	Aa 77–83
P140 (KIR3DL2)	HLA-A3, -A11	
(KIR2DL4)	HLA-G	

Aa, Amino acid; *Asn*, asparagine; *HLA*, human leukocyte antigen; *KIR*, killer immunoglobulin-like receptor; *Lys*, lysine; *Ser*, serine.

Like HLA, KIR genes are polymorphic, and their variability is clustered in positions likely to affect the overall structure of the molecule. The relevance of KIR gene polymorphism in the outcome of bone marrow transplantation (BMT) is unclear. It appears that the risk for GVHD is highest in the context of unrelated BMT when the recipient KIR genotype is included in the donor KIR genotype.[99] These results show that compatibility between KIR genotypes themselves may influence the outcome of BMT.

The minor histocompatibility antigens (mHags) are represented by polymorphic molecules whose peptides containing variant sequences are presented by HLA alleles. They have been shown to be targets of cytotoxic T cells, which can lyse leukemia cells.[98,100] In addition, some mHags are selectively expressed by neoplastic cells.[101] At present, little is known about the identity of mHag epitopes in the context of various HLA types and their significance in the development of GVHD and GVN.

Cytokines are another large family of molecules associated with antigen recognition, graft rejection, and GVHD. Their polymorphism is becoming an important area of investigation in the context of transplantation, autoimmunity, and cancer.[102] Polymorphic sites reside in regulatory regions so that genetic variants are associated with high or low production of a given cytokine rather than differences in its function. A website compiles information about cytokine polymorphism (www.bris.ac.uk/Depts/PathAndMicro/services/GAI/cytokine4.htm). Although no consensus has been achieved yet, several studies have shown associations between various cytokine genotypes, the propensity for disease, and transplant outcome. These studies have been summarized elsewhere.[92,103] A strong association was recently noted between a low interleukin-10 producer genotype and a tendency to develop melanoma and prostate cancer.[104,105]

HUMAN LEUKOCYTE ANTIGEN NOMENCLATURE

The history of the HLA system nomenclature was summarized by Sir Walter Bodmer who, together with Ruggero Ceppellini, was primarily involved in its development.[106] It began as HL-A, for *human leukocyte locus A*. With the recognition that HLA molecules are encoded by more than one locus, the A came to stand for *antigen*, and a locus designation was added after HLA (i.e., HLA-A, -B, -C, -D, etc.)[2]. From then on, the WHO has updated nomenclature on a quarterly basis. The most recent update was assigned in January 2015, as seen in Table 114.2.[4] At present, two systems are used. An immunologically defined nomenclature is based on the identification of HLA antigens on the surface of leukocytes. Therefore, HLA phenotypes described by immunologic methods are conventionally called *HLA antigens*.[107] The second system is based on the molecular identification of nucleotide sequences in genomic deoxyribonucleic acid (DNA), and results are conventionally referred to as *HLA alleles*. Because molecular typing has a higher resolution, it has gained increasing popularity.

IMMUNOLOGICALLY DEFINED HUMAN LEUKOCYTE ANTIGEN NOMENCLATURE

Immunologically defined nomenclature follows this rule: HLA separated by a hyphen from a capital letter identifying the locus encoding distinct HLA class I (-A, -B, -C) or class II (-DR, -DQ, -DP) antigens. The letter is followed by a number that identifies a serologic family of alleles sharing epitopes recognized by alloantibodies or alloreactive cytotoxic T cells. With improved understanding of the molecular genetics of the HLA region, various appendages have been removed from the HLA nomenclature. For instance, the letter *w* was used to indicate a provisional assignment, and this has been discontinued, but it is occasionally added to HLA-C antigen nomenclature to distinguish it from complement genes; DP and DW also maintained this letter to reinforce the dependency of their immune identification predominantly through cellular techniques. Finally, HLA-Bw4 and -Bw6 retain the *w* to emphasize that the public epitopes are shared by several HLA-B and some HLA-antigens. More recently, a bridge between immunologic and molecular nomenclature has been proposed whereby HLA antigens that encompass a single gene product can be assigned a two-digit numeric extension corresponding to the molecular nomenclature for that allele.[108]

SEQUENCE-DEFINED ALLELIC NOMENCLATURE

In 1987, the 10th International Histocompatibility Workshop recommended a sequence-based nomenclature[108] to describe alleles not distinguishable by immunologic methods. Since then, the number of HLA alleles has rapidly increased. As of January 2015, a total of 13,023 alleles for HLA exist. This is a drastic increase from the original numbers established in 2003. Other designations are summarized in Table 114.2. HLA designates molecules belonging to the human MHC followed by the locus (-A, -B, etc). Alleles are then identified after an asterisk (*). Each HLA allele name has a unique number corresponding to up to four sets of digits separated by colons. The length of the allele designation is dependent on the sequence of the allele and that of its nearest relative. All alleles receive at least a four-digit name, which corresponds to the first two sets of digits; longer names are only assigned when necessary. The digits before the first colon describe the type, which often corresponds to the serological antigen carried by an allotype. The next set of digits is used to list the subtypes, numbers being assigned in the order in which DNA sequences have been determined. Alleles whose numbers differ in the two sets of digits must differ in one or more nucleotide substitutions that change the amino acid sequence of the encoded protein. Alleles that differ only by synonymous nucleotide substitutions (also called silent or non-coding substitutions) within the coding sequence are distinguished by the use of the third set of digits. Alleles that only differ by sequence polymorphisms in the introns or in the 5′ or 3′ untranslated regions that flank the exons and introns are distinguished by the use of the fourth set of digits.[109] A four-digit number is used in which the first two digits refer to the original serologic family (e.g., HLA-A2 serologically would be HLA-A*02). Often numbers are missing because an original assignment was revoked (e.g., this is why there is no HLA-A*24:01). When silent mutations are identified (variation in nucleotide sequence that does not translate into changes in amino acid sequence), the name of the allele remains identical, but another two digits are added to designate a variant that has no functional significance. New sequences are submitted to European Molecular Biology Laboratory (EMBL; www.ebi.ac.uk/Submissions/index.html), GenBank (www.ncbi.nlm.nih.gov/Genbank/index.html), or DNA Data Bank of Japan (DDBJ; http://www.ddbj.nig.ac.jp/submission-e.html).

Requirements for new allele naming were described by Marsh et al.[4] The WHO Nomenclature Committee also made recommendations about naming alleles with aberrant expression, such as HLA-G isoforms and KIR. Some alleles are identifiable at the genomic level but are not translated into protein (pseudogenes). These are indicated by the addition of an *N* (for null) following the numerical designation of the allele. Mutations inducing a reduction of expression are marked by *L* (low expression). An *S* denotes alleles expressed as soluble secreted molecules, such as HLA-B*44:02:01:02 S characterized by an intronic variant that disallows the expression of the transmembrane domain of the HLA molecule and is therefore only in soluble form. Differential splicing of HLA-G leads to production of membrane-bound and soluble forms, which are respectively denoted by a lowercase *m* or *s* before HLA. Limited cytoplasmic expression is denoted by *C* and aberrant expression by *A*. Finally, KIR polymorphism will be classified by a new system that is in preparation.[4,97,110] A nomenclature system for cytokine polymorphism has not yet been developed.[111]

HUMAN LEUKOCYTE ANTIGEN TYPING IN CLINICAL HEMATOLOGY AND DETERMINATION OF COMPATIBILITY HUMAN LEUKOCYTE ANTIGEN TYPING

Originally HLA typing was done primarily in support of transplantation or transfusion needs with the purpose of identifying histocompatibility through the best match between donor and recipient. Allosensitization of recipients previously exposed to heterologous cell products is tested by identifying alloreactive antibodies in serum, and crossmatch procedures are performed to grade compatibility of candidate donor-recipient pairs. In addition, HLA testing has been applied to identify links between a given disease and the genetic makeup of its carriers.[112] Strong associations are exemplified by birdshot uveitis (a disease occurring exclusively in HLA-A29 individuals),[113] type 1 diabetes and other autoimmune diseases,[114–116] or long-term survival of HIV-infected individuals.[55] These studies evaluated the role that genetic background may have played over environmental factors.[112,117] HLA associations are thought to be caused by the differential ability of distinct alleles to present immunogenic epitopes[113,115] or by the close linkage to the HLA class III region where potent immunomodulators such as tumor necrosis factor-α are located.[118] It has also been suggested that HLA associations may be predictors of immune responsiveness of cancer to immune therapy.[60] However, such associations have remained quite difficult to reproduce.[119] HLA typing is requested for enrollment of patients into and interpretation of immunization protocols,[24] because specific HLA-epitope combinations require high-resolution typing.[22,120]

Serologic testing takes advantage of fetomaternal sensitization. In mammals, the progeny carries a full haplotype of paternal origin, and pregnant women may develop antibodies against the paternal haplotype. Maternal serum samples are collected at term and characterized by testing their ability to kill HLA-bearing repository cell lines of known phenotype in the presence of complement (complement-dependent

TABLE 114.2 Name of Genes in the HLA Region Considered by the WHO Nomenclature Committee

Name	Previous Equivalents	Molecular Characteristics	No. of Alleles January (2015)
HLA-A	–	Class I α-chain	3107
HLA-B	–	Class I α-chain	3887
HLA-C	–	Class I α-chain	2623
HLA-E	E, “6.2”	Associated with class I 6.2-kBa Hind III fragment	17
HLA-F	F, “5.4”	Associated with class I 5.4-kBa Hind III fragment	22
HLA-G	G, “6.0”	Associated with class I 6.0-kBa Hind III fragment	50
HLA-H	H, AR, “12.4”, HLA-54	Pseudogene association with class I 5.4-kBa Hind III fragment	12
HLA-J	cda 12, HLA-59	Pseudogene association with class I 5.9-kBa Hind III fragment	9
HLA-K	HLA-70	Pseudogene association with class I 7.0-kBa Hind III fragment	6
HLA-L	HLA-92	Pseudogene association with class I 9.2-kBa Hind III fragment	5
HLA-X	–	Class I gene fragment	0
HLA-DRA	DRα	DR α-chain	7
HLA-DRB1	DRβI, DR1B	DR β_1 determining specificity for DR1, DR2, DR3, etc.	1726
HLA-DRB2	DRβII2	Pseudogene with DRβ-like sequence	1
HLA-DRB3	DRβIII, DR3B	DR β3 determining DR52, Dw24, w25, -26 specificity	59
HLA-DRB4	DRβIV, DR4B	DR β4 determining DR53 specificity	15
HLA-DRB5	DRβV, DR5B	DR β5 determining DR52, Dw24, w25, -26 specificity	21
HLA-DRB6	DRBX, DRBσ	Pseudogene found in DR1, DR2, and DR10 haplotypes	3
HLA-DRB7	DRBψ1	Pseudogene found in DR4, DR7, and DR9 haplotypes	2
HLA-DRB8	DRBψ2	Pseudogene found in DR4, DR7, and DR9 haplotypes	1
HLA-DRB9	M 4.2 β exon	Pseudogene isolated fragment	1
HLA-DQA1	DQα1, DQ1A	DQ α-chain as expressed	54
HLA-DQB1	DQβ1, DQ1B	DQ β-chain as expressed	780
HLA-DOA	DNA,DZα, DOα	DO α-chain	12
HLA-DOB	DOβ	DO β-chain	13
HLA-DMA	RING 6	DM α-chain	7
HLA-DMB	RING 7	DM β-chain	13
HLA-DPA1	DPα1, DP1A	DP α-chain as expressed	33
HLA-DPB1	DPβ1, DP1B	DP β-chain as expressed	520
TAP1	ABCB2, RING4	ABC (ATP-binding cassette) transporter	12
TAP2	ABCB3, RING 11	ABC (ATP-binding cassette) transporter	12
MICA	PERB 11.1	Class I chain–related gene	101
MICB	PERB 11.2	Class I chain–related gene 18	41

ATP, Adenosine triphosphate; *HLA*, human leukocyte antigen; *WHO*, World Health Organization.

cytotoxicity [CDC]).[121] CDC is used for HLA typing by exposing circulating cells expressing HLA class I (most cells) and class II (predominantly B cells) antigens from the individual (to be typed to previously characterized sera or monoclonal antibodies).[122] Conversely, already typed repository cell lines are used in CDC to identify alloantibodies in sera of sensitized individuals. The fraction of cell lines killed by the sera roughly grades the intensity of allosensitization or panel reactive antibody (PRA) reactivity. Some antibodies activate complement and kill with poor efficiency, known as the *cytotoxicity-negative absorption-positive (CYNAP) phenomenon*.[123] As judged by cytotoxicity testing, CYNAP may underestimate allosensitization. By modifying CDC with the addition of antihuman antibodies suitable for complement activation, CYNAP can be circumvented (augmented CDC). In this case, however, relatively innocuous antibodies can cause overestimation of clinically relevant allosensitization.[124]

Other methods identify alloantibodies, including immobilization of HLA molecules on solid surfaces to capture soluble antibodies[125–127] and flow cytometry using a spectrum of microbeads loaded with known HLA alleles.[128,129] An interlaboratory comparison of serum screening for HLA-antibody determination suggested that enzyme-linked immunosorbent assay and flow cytometry yield higher PRA activity values compared with CDC or augmented CDC.[125,127] However, the study suggested a lack of consistency among participant laboratories, leaving unsolved the question of which method most accurately defines clinically relevant allosensitization, and a panel of various methods may be most informative.[72]

CDC is declining in interest in the United States because most laboratories are switching to easier-to-handle and higher-resolution molecular methods. However, immunologic methods remain valuable to characterize functional aspects of HLA because molecular methods cannot define whether an HLA allele is expressed nor, at least until recently,[130] grade allosensitization. Thus it is likely that immunologic methods will continue to complement molecular methods in the future.[130]

The usefulness of conventional serologic typing of HLA antigens has been limited by the availability of allele-specific sera. Most importantly, because antibodies identify structural differences on the surface of HLA molecules, variants caused by nucleotide polymorphism in nonexposed areas such as the peptide-binding groove of the HLA heavy chain are not detectable. However, these differences are of functional significance because they determine the specificity and affinity of peptide binding[131,132] and T-cell recognition of self and allogeneic target cells.[23,133] DNA-based typing directly determines the sequence[134] and provides higher resolution typing.

DNA-based typing can be performed with polymerase chain reaction (PCR)-based methods, among which are sequence-specific primer,[134,135] sequence-specific oligonucleotide probe,[136,137] and DNA sequencing.[138] Molecular typing using sequence-specific oligonucleotide primers or probes provides higher level typing than serological typing, and DNA sequencing provides allele-level typing.[138] The rich nature of HLA has led to proportionally increasing complexity of the assays used to cover all possible alleles. As a consequence, accurate HLA typing for donor and recipient matching in transplantation has become increasingly complex and burdensome. In addition, because of the important role that HLA molecules play in antigen presentation and the stringency of the relationship between epitope and associated HLA allele, high-resolution typing is increasingly requested for appropriate enrollment of patients into immunization protocols aimed at the enhancement of T-cell responses.[139] Therefore high-resolution HLA typing is increasingly in demand in clinical and experimental settings.

Although oligonucleotide-based methods could theoretically discriminate any known polymorphic site, they have two major limitations. First, they require a specific PCR reaction for each allele investigated. Because each individual has only two alleles for each locus, a disproportionately large number of PCR reactions must be performed to cover all possible polymorphisms to identify the two borne by the individual tested. Because both methods are based on specific interactions with known oligonucleotide sequences unique to a particular allele, they cannot identify unknown polymorphisms unless the variation occurs within the region spanned by one of the oligonucleotides used in the assay. Because of these limitations, definitive typing methods that yield conclusive information about the identity of the alleles typed using DNA sequence-based typing have been developed.

Sequence-based typing is being performed using Sanger sequencing and next generation sequencing.[138,140] Most methods begin with PCR amplification of the HLA locus of interest. Sanger sequencing involves chain termination sequencing techniques and does not allow the separation of sequences of maternally and paternally derived alleles. Sanger sequencing cannot distinguish *cis*/*trans* polymorphisms since both alleles are sequenced in one reaction and it is difficult to determine if two variants are from the same chromosome (*cis*) or from the opposite chromosome (*trans*).[140a] Therefore, some combinations of HLA class I and class II alleles result in ambiguous allele combinations that require additional testing for resolution.[141] Sanger sequencing instruments analyze only one sample at a time, which limits sample throughput and further limits the usefulness of this technology.

Next-generation sequencing allows for the parallel sequencing of multiple single strands of DNA. This allows for the determination of the sequence of both maternal and paternal HLA sequences, which reduces ambiguities. It also provides information on HLA genes not previously sequenced, allowing for the identification of new alleles.[142] Next-generation sequencing instruments permit the analysis of many samples at one time, allowing for high throughput analysis and reduces costs.[138,140] A number of next-generation sequencing technologies and instruments are available.

High-resolution methods yield high-resolution information of an individual's HLA type. However, the wealth of information is counterbalanced by increased difficulty in identifying suitable HLA alleles during donor-recipient pairing or accrual into immunization protocols restricted to specific HLA-epitope combinations. Thus, at present, clinicians are faced with the daunting task of applying high-resolution typing results of unclear relevance to clinical settings.[143]

TESTING FOR ALLOSENSITIZATION AND DETERMINATION OF COMPATIBLE DONOR-RECIPIENT PAIRS

Any cell-containing product transfused or transplanted between different individuals should be compatible in an ideal situation. Yet, in most cases, histocompatibility is not prospectively sought. Thus patients with multiple exposures to blood products often become reactive to various antigens, including HLA. Transplant candidates often develop prior alloreactivity following transfusion of platelet concentrates contaminated with leukocytes, even though the incidence of allosensitization is much less because of leukodepletion of blood products. Alloreactivity must be documented before transplantation because alloreactive patients can still undergo transplantation, provided that the donor has no mismatched HLA antigens reacting with the patient's antibodies. Patients who have received repeated platelet transfusions may become allosensitized and consequently refractory to further transfusions unless HLA-compatible platelets are used. Obviously, the best compatibility consists of identical matching. It is often impossible to identify a perfectly matched unrelated donor, particularly in the case of rare HLA types. Thus other strategies are adopted to identify the best possible match or compatible mismatch. Selection of unrelated donor-recipient pairs is carried out through typing with serologic, cellular, and molecular methods.[144] The chances of identifying compatible donors based on full or partial HLA matching have become increasingly low with the increasing resolution of the typing methods.[143] To broaden compatibility, matching criteria of donor-recipient pairs are based on shared public epitopes assigned to cross-reactive groups (CREGs)[145] or shared amino acid polymorphisms defined through sequence information (Table 114.3).[146] The preexistence of alloantibodies restricts the identification of compatible donors even further. Highly sensitized recipients with PRA activity exceeding 85% of tested specificities (generally between 30 and 60) represent a particularly challenging group.[147] An alternative approach to the exclusion of alloreactive determinants is the inclusion of acceptable antigen mismatches expressed in a panel of cells that give negative reactions with the recipient sera,[148] which extends the repertoire of possible donors. All of these are fundamental tools for the identification of nonrelated, not fully matched donor-recipient pairs. Unfortunately, even these compromises often fail to identify a suitable match.

Duquesnoy[147] described a molecularly based algorithm to identify histocompatible pairs called HLAMatchmaker. This method focuses on the structural basis of HLA class I polymorphism so that compatible HLA mismatches can be identified without extensive serum screening. This algorithm is based on the principle that short amino acid sequences (triplets) characterizing polymorphic sites of the HLA molecules are critical components of allosensitizing epitopes. Such amino acids reside in the α-helices and β-loops of the heavy chain. Because each HLA molecule expresses a characteristic string of these determinants, it is possible to characterize each molecule according to the linear sequence of amino acid triplets present on its surface. Based on the reasonable assumption that none of the triplets present in the HLA repertoire of the recipient is self-immunogenic, it is possible through a process of electronic recombination to identify donors with HLA alleles different from the recipient's but containing exclusively shared triplets. These HLA alleles will be compatible because they do not contain any epitope that is absent in the recipient.

In theory, a large number of triplets could occur if polymorphisms were randomly distributed. However, most HLA molecules span conserved domains, and only a total of 142 different polymorphic triplets designate serologically defined HLA-A, -B, and -C antigens.[147] Triplet polymorphism can occur in 30 locations on HLA-A, 27

TABLE 114.3 **Population Frequencies of Major Cross Reactive or Determinants Present on HLA-A and -B Gene Products**

Major Cross-Reactive Group	Public Epitope	Associated Private Epitopes	Approximate Epitope Frequency (%)[a]
1C	1p	A1, 3, 9 (23, 24), 11, 29, 30, 31, 36, 80	79
	10p	A10 (25, 26, 34, 43, 66), 11, 28 (68, 69), 32, 33, 74	
2C	28p	A2, 28 (68, 69), 9, 17	70
	9p	A2, 28 (68, 69), 9 (23, 24)	
	17p	A2, B17 (57, 58)	
5C	5p	B5 (51, 52), 18, 35, 53, 78	50

[a] North American White populations of European origin.

in HLA-B, and 19 in HLA-C chains. Because the HLAMatchmaker algorithm includes interlocus comparison, it is possible to accumulate the information into a single database. Among the 142 polymorphic triplets, 29 are polymorphic for one class I locus but monomorphic for another class I locus. Such polymorphic triplets cannot be immunogenic because they are always present on the patient's own HLA antigens, whereas the remaining 113 triplets have immunogenic potential. With this algorithm, it is possible to significantly broaden the number of molecularly matched HLA alleles and significantly increase the chances of identifying a compatible donor, particularly in those cases in which the recipient has a rare HLA phenotype. In addition, HLAMatchmaker considers triplets that are present in the panel cells that give negative reactions with the recipient's serum. These negative panel cells can be expected to share antigens with the patient's, but other HLA antigens may be present and contain mismatched triplets apparently not immunogenic for that patient. Such triplets are therefore acceptable and can be added to the algorithm for the identification of possible donors. Thus HLAMatchmaker assesses HLA compatibility at a molecular level by determining whether or not a triplet in a given position of a mismatched HLA antigen is also found in the same position in any of the recipient's own HLA-A, HLA-B, and HLA-C molecules. A shared triplet in the same position on a mismatched HLA antigen cannot elicit a specific antibody response in that patient. Preliminary verification of the algorithm in a series of high-PRA renal patients suggested that this is a proper strategy, at least in highly sensitized renal transplantation candidates waiting for unrelated donors.[149,150] HLAMatchmaker is also effective at selecting an optimal HLA-typed platelet component for alloimmunized thrombocytopenic patients.[150]

A new version of HLAMatchmaker considers so-called eplets and is based on the structural definitions of functional epitopes on well-characterized protein antigens that have been complexed with antibody.[151] Eplets represent amino acid residue configurations within a 3- to 3.5-Å radius of each polymorphic residue on the HLA molecular surface. Many eplets correspond to triplets, but eplets represents a more complete repertoire of structurally defined epitopes.

THE HUMAN LEUKOCYTE ANTIGEN MOLECULES AS ANTIGENS AND HUMAN LEUKOCYTE ANTIGEN ALLOIMMUNIZATION

By no means are HLA molecules antigenic in physiologic condition (with the exception of maternofetal alloimmunization). However, because of their high density on the surface of cells, they can become highly immunogenic in the nonphysiologic event in which cells from different individuals are exposed to another person's immune system. The mechanism or mechanisms leading to allosensitization are believed to follow two pathways. The first pathway mimics the one followed during most immune reactions in which antigen is uptaken by antigen-presenting cells and presented to autologous lymphocytes (indirect pathway). In this case, the donor's HLA molecules are processed into peptides through the exogenous pathway of antigen presentation and presented to autologous T cells as linear peptides.[152,153] This pathway is believed to be responsible for the development of alloantibodies as well as T-helper cell responses, but its role in the development of cytotoxic T-cell responses remains unclear. Because this pathway depends on the presentation of donor HLA molecules by recipient HLA alleles, it may explain why the humoral response to HLA class I allodeterminants correlates with the HLA phenotype of the responder.[154] The indirect pathway of HLA allorecognition has been associated with allograft rejection.[155] Because the function of HLA molecules is to present antigenic determinants to T cells, it could be easily envisioned how minor changes in their structure could be misinterpreted as antigenic epitopes. Intact HLA molecules residing on the surface of donor cells are a perfect target for T-cell-mediated allorecognition (direct pathway) either through the direct cytotoxic effect of T cells against target cells or by the activation of helper T cells through HLA class II engagement, which leads to stimulation of antibody-mediated immune responses.[156]

Humoral responses mediated most frequently by IgM are predominant in the sensitization to infrequent allogeneic exposure because they require smaller amounts of antigenic material. T-cell responses become more manifest in the context of transplantation in which the persistence of the allogeneic stimulus allows the expansion and sustenance of alloreactive cytotoxic T cells. Antibodies and TCR have different requirements for their engagement, which means epitopes recognized by T cells and antibodies are different. Antibodies require interaction with a small structure, including a limited number of amino acids; thus, any sequence combination on the surface of an HLA allele not present in the individual exposed to the alloreaction may represent an epitope. T cells have much lower binding affinity for their ligand and require a complete interaction with the peptide as well as the α and β helices of the HLA class I heavy chain.[11] Although several B-cell epitopes recognized by antibodies can be identified in a given HLA molecule, generally the whole HLA molecule is necessary for T cell–dependent allorecognition. Definition and topographic mapping of epitopes defined by serologic or cellular methods has revealed distinct regions of hypervariability in the α-1 and α-2 domains of the class I heavy chains and in the α-1 and β-1 domains of class II molecules.[157] Two types of antibody-defined epitopes can be identified according to their frequency among HLA alleles. Private epitopes are almost but not totally unique for a single serologically defined HLA antigen and are used for typing. These epitopes are generally shared by all molecular alleles present in that given family, and fine differences among alleles within a general family cannot be distinguished by antibodies. Public epitopes are more widely distributed and cluster distinct serologic families into groups. These epitopes bear an immunodominant character. Immune sera that identify public epitopes have been considered predictive of major CREGs with the idea that alloreactivity among patients belonging to the same CREG may be less likely (see Table 114.3). The predictive value of CREGs in transplant outcome or platelet transfusion results, however, remains to be demonstrated.

Not all subjects who have been exposed to alloantigens develop alloantibodies, and in fact exposure to low doses of donor-specific HLA antigens through donor transfusion may have a beneficial effect on graft survival.[158] Obviously, the degree of compatibility in the context of allosensitization may vary according to the degree of mismatch between donor and recipient. In addition, alloantibodies are one aspect of alloreaction that does not take into account cellular responses. These have been more difficult to document, although they are likely to play an important role in the context of acute transplant rejection. Several hypotheses have been discussed about the reason or reasons for the capriciousness of allosensitization, including the presence of regulatory immune responses or cytokine-mediated immunosuppression. Currently the mechanism modulating the quality and quantity of alloimmunity remains elusive, and different aspects of this algorithm are discussed ad hoc in this chapter, with particular attention to molecularly defined algorithms for the prediction of histocompatibility.[130,147,159,160]

Clearly, HLA matching is beneficial in patients undergoing renal transplantation. An analysis of more than 150,000 recipients receiving transplants in different centers participating in the Collaborative Transplant Study showed that a complete mismatch (6 HLA-A+B+DR) had a 17% lower survival expectation than no mismatch ($P < .0001$).[161] Matching was particularly beneficial in patients with highly reactive preformed alloantibodies. The same study suggested that high-resolution matching based on molecular typing improved graft survival. Similar results were observed in cases of cardiac transplantation in which HLA matching yielded significantly better results ($P < .0001$). This is particularly important because donor hearts are currently not allocated according to HLA matches in most centers. In cases of liver transplantation, HLA matching was not beneficial.[162]

Donor-specific hyporesponsiveness has been particularly well documented in the context of renal allotransplantation and may limit the need for immunosuppression. A recent randomized study suggested that pretransplant donor transfusions improved the survival of cadaver kidney grafts in patients receiving modern immunosuppressive regimens, but the mechanism remains unclear.[163,164] Although most centers currently do not implement deliberate blood transfusions, the usefulness of this approach needs to be investigated further.

Approximately 5% to 10% of platelet transfusions are given to patients who have been previously exposed to HLA class I–expressing heterologous cells and are reactive to HLA antigens. Such patients are refractory to random-donor platelets and must be given HLA-matched or semi-matched platelet pheresis components.[41–44] However, a provision of HLA-matched platelets does not always improve platelet recovery and survival. Possibly, the ineffective platelet transfusion is in part caused by unrecognized HLA mismatches between the donor and recipient resulting from the low-resolution methods used for typing, and higher resolution methods have been advocated. It is currently controversial whether or not molecularly based HLA typing confers an advantage over serologic typing, and this principle was recently questioned in the context of hematopoietic cell transplantation.[165,166]

HUMAN LEUKOCYTE ANTIGEN AS A FUNCTIONAL MEDIATOR OF GRAFT-VERSUS-HOST DISEASE AND/OR GRAFT-VERSUS-NEOPLASIA EFFECT

Allogeneic or syngeneic BMT is used predominately for the treatment of hematologic malignancies[167–169] and other hematologic disorders such as aplastic anemia,[170] thalassemia,[171] or myelodysplastic syndrome.[172] This strategy can induce long-term disease-free survival in chronic myelogenous leukemia patients.[167,169] The objective of BMT in cases of malignancy is to cure the patient by eradication of the neoplastic cells with myeloablative chemotherapy followed by restoration of hematopoiesis through the transplantation of normal hematopoietic stem cells derived from HLA-compatible normal donors. This strategy is characterized by the insurgence of an immune reaction toward the host's normal cells (GVHD),[173–175] which is often associated and preferentially targets neoplastic cells (GVN effect).[176–183] Both the GVHD and the GVN effect occur in the presence of a full HLA match; thus the HLA molecules are not targets of allosensitization themselves but present polymorphic molecules expressed by the recipient's cells recognized by the grafted immune cells.

GRAFT-VERSUS-HOST DISEASE

GVHD represents the alloimmune reaction of donor lymphocytes against normal cells of the recipient. GVHD occurs predominantly in association with hematopoietic progenitor cell transplantation (HPCT) compared to other types of transplants because the hematopoietic transplant is enriched with immune cells. Myeloablative therapy is generally administered before transplantation and, as a consequence, prevents graft rejection in most cases. GVHD is a major complication of HPCT, and a fine balance between GVHD and graft rejection is maintained by modulating the level of post-transplantation immunosuppression.[177] In addition, other major disturbances associated with HPCT, such as overwhelming infection, leukemia, tumor relapse, and other regimen-related morbidities are strongly influenced by the treatment of GVHD. With the advent of nonmyeloablative HPCT for the treatment of nonhematologic diseases such as solid tumors, GVHD has reached a predominant role because of its close association with the GVN effect.

T-cell depletion has been advocated for the prevention of GVHD by decreasing the probability of cellular and humoral alloresponses.[184,185] This strategy decreases the occurrence of GVHD but is associated with an increased risk for graft rejection and tumor or leukemia relapse.[177] In fact, Weiden et al.[186] observed that survivors of severe acute GVHD had a significantly lower incidence of tumor relapse compared with patients who did not experience GVHD. This association appeared mandatory, and it was believed that the beneficial GVN reaction was inseparable from GVHD.

The risk for GVHD increases with genetic distancing between donor and recipient. Thus recipients of transplants from HLA-identical twins have a lesser chance of developing GVHD than recipients of transplants from HLA-unrelated donors and from donors with only a partial HLA match.[187,188] Interestingly, however, although the genetic closeness between donor and recipient appears to decrease the risk for GVHD, it also decreases the therapeutic benefit, with increased chances of tumor relapse.

GRAFT-VERSUS-NEOPLASIA EFFECT

It was originally observed that a beneficial collateral effect of GVHD was the rejection of neoplastic cells by the donor immune system in the context of hematologic malignancies (graft-versus-leukemia effect).[181] It was rapidly recognized that the graft-versus-leukemia effect could play a powerful therapeutic role in the treatment of refractory malignant disorders, including some solid tumors (graft-versus-tumor effect).[178] Because the biology and clinical principles underlining the two effects are likely similar, for simplicity, in this chapter we coin a unifying term: *graft-versus-neoplasia effect*. Indeed, there is a perception that the GVN reaction is the most potent form of tumor immunotherapy currently in clinical use. Its mechanism of action is still poorly understood. T cells definitely play a fundamental role in the initiation and maintenance of the alloreaction toward neoplastic cells.[189] A sevenfold increase in the chance of relapse was noted in patients with chronic myelogenous leukemia who received a T-cell-depleted BMT as compared with a subset of patients who had received a T-cell-repleted BMT but did not develop GVHD.[184,185] This result suggested that GVHD is a biologic entity different from the GVN effect. In addition, on leukemia relapse, administration of donor lymphocyte infusion could reinduce clinical remission.[190] Finally, leukemia-specific CD8$^+$ T cells have been identified in circulating lymphocytes at the time of leukemia regression.[191] NK cells play an additional role in mediating this phenomenon, and clinical data suggest that mismatch of NK receptor and ligands during allogeneic BMT can be used to enhance the GVN effect.[93,192] Appreciation of the GVN effect has led to the development of nonmyeloablative stem cell transplants designed to immunosuppress the host to a level sufficient to permit engraftment of the donor immune cells to generate GVN without inducing the serious complications associated with myeloablation.[177] The GVN effect has gained popularity in the last decade to the point that allogeneic-based immunotherapeutic approaches have been advocated for several nonhematologic malignancies.[177] The rationale is largely based on the assumption that the immune cell repertoire capable of recognizing cancer cells in the allogeneic context is broader than in the autologous system. Donor T cells can target not only tumor-specific antigens but also allelic variants of these antigens, mHag, and, in the case of HLA-mismatched transplants, HLA antigens disparate from the donor expressed by the tumor cells.[193–195] Although there are several theories about how the GVN effect occurs, it remains unclear why allo-T cells have a better chance of targeting tumor cells in an allogeneic context as compared with the natural insurgence of antitumor immunity described for several solid tumors.

HUMAN LEUKOCYTE ANTIGEN AND T-CELL-DIRECTED IMMUNIZATION

The last decade has witnessed remarkable progress in the identification and mapping of T-cell epitopes for various infectious diseases and cancer. In particular, progress was made in mapping HLA-associated epitopes for HIV, cytomegalovirus, and Epstein-Barr virus.[196–199] In addition, the molecular identification of tumor-associated antigens has yielded a large number of epitopes that could be used to immunize against neoplasia.[200] A comprehensive discussion of these topics is beyond the scope of this chapter, but we address a few points framing the relevance of HLA in the context of T-cell-directed immunization (viral specific T cells).

The identification of T-cell epitopes led to two major areas of clinical investigation. The first is active-specific immunization to prevent or treat ongoing infections or cancer. The second is the harvest and in vitro expansion of immunization-induced T cells for adoptive transfer. In general, active immunization has proved successful in inducing epitope-specific T cells easily detectable among circulating lymphocytes.[120,201–203] However, often the immunization-induced enhancement of T-cell function is not associated with clinical improvement. Although the reason for the clinical ineffectiveness of immunization-induced T cells is unclear, it has been postulated that they may be quantitatively[201] or qualitatively[204] inadequate for eradicating disease. Therefore a second strategy is being pursued whereby the number of antigen-specific T cells is amplified in vitro for autologous or donor-derived adoptive transfer. This second strategy has met some promising success in the context of ganciclovir-resistant cytomegalovirus infection,[205] Epstein-Barr virus–induced posttransplantation lymphoproliferative disorders,[206] and metastatic melanoma.[207]

Whether delivered as a primary form of therapy or to prime in vivo T cells for further ex vivo expansion, epitope-specific vaccination encounters the major limitation of a stringent requirement for HLA allelic association. Although super families of HLA alleles may share epitopes,[14,16] in practical terms, clinically relevant HLA-epitope associations are restricted to few peptide-allele combinations for a given protein.[22] Patients considered for enrollment in immunization protocols are best served by high-resolution HLA typing to exclude subtypes with unproven immunogenic potential for a given epitope. To bypass the stringent HLA requirements demanded by epitope-specific vaccination, whole-antigen delivery is suggested. This is based on the assumption that the epitope repertoire of a protein can be adjusted to distinct HLA phenotypes by a cellular process of self-selection naturally coupling peptides to HLA according to binding affinity. Although theoretically indisputable, in practice, the truth of this assumption depends on the efficiency with which individual molecules are processed and presented in association with distinct HLA alleles. Even in these settings, high-resolution typing is desirable because it allows accurate interpretation of immunization results by allowing a comparison between the detailed genetic makeup of the individual receiving the vaccine and his or her antigen-specific immune response. It is likely that in the future HLA laboratories will receive increasing demands for high-resolution, definitive typing for appropriate patient enrollment and for subsequent interpretation of immune responses.

MONITORING IMMUNE RESPONSES WITH TETRAMERIC HUMAN LEUKOCYTE ANTIGEN-PEPTIDE COMPLEXES

A growing understanding of the molecular immunology of T-cell interactions with HLA/epitope complexes in the context of infectious disease, virally induced malignancies, and spontaneous tumors as well as interest in their treatment with T-cell-directed vaccines has generated more attention to the issue of using accurate methods to quantify ex vivo the extent of antigen-specific immune responses.[208] The most commonly used assays available for the enumeration of antigen-specific T cells include tHLA; intracellular fluorescence-activated cell sorter staining for cytokine expression on cognate stimulation; detection of cytokine release by enzyme-linked immunospot assay; and quantitative real-time PCR, recently reviewed by Keilholz et al.[209] tHLAs are complexes of four HLA molecules combined with a specific peptide and bound to a fluorochrome (Fig. 114.6). These complexes bind to complementary TCR and identify antigen-specific T cells,[210] measuring cellular responses against specific epitopes with sensitivity as low as 1 in 5000 CD8$^+$ T cells. To synthesize tHLA molecules, soluble HLA heavy chains containing a biotinylation site and recombinant β_2-microglobulin are synthesized and purified. They are then refolded in the presence of the specific epitope, and the monomer is isolated by gel filtration and is biotinylated. Fluorescent streptavidin is added to induce tetramerization. An aliquot of tetramers is added to the peripheral blood mononuclear cells together with other antibodies for a more detailed characterization of antigen-specific T cells.[204] Analysis is performed using a flow cytometer. Because of the specificity of vaccines, the patient's HLA type and specific peptide must be identified and synthesized to provide the adequate tetramer. Pentameric HLA/peptide complexes have recently become available and in some laboratories have replaced the use of tHLA.

Analysis of tHLA offers many potential advantages over other T-cell assays. This method is quantitative and enables an estimation of the avidity between TCR and peptide-loaded HLA class I molecules. tHLA staining does not kill the labeled cells, allowing sorting of subpopulations by flow cytometry for additional analysis or expansion for adoptive transfer. With tHLA specific T cells can be analyzed from blood samples without the prerequisite of in vitro culture, and all specific cytotoxic T lymphocytes are detected, regardless of their functional status.[201,204,211]

HUMAN LEUKOCYTE ANTIGEN SUMMARY

The relevance of HLA in clinical pathology has broadened from its role as a predictor of allosensitization to a mediator of GVHD and

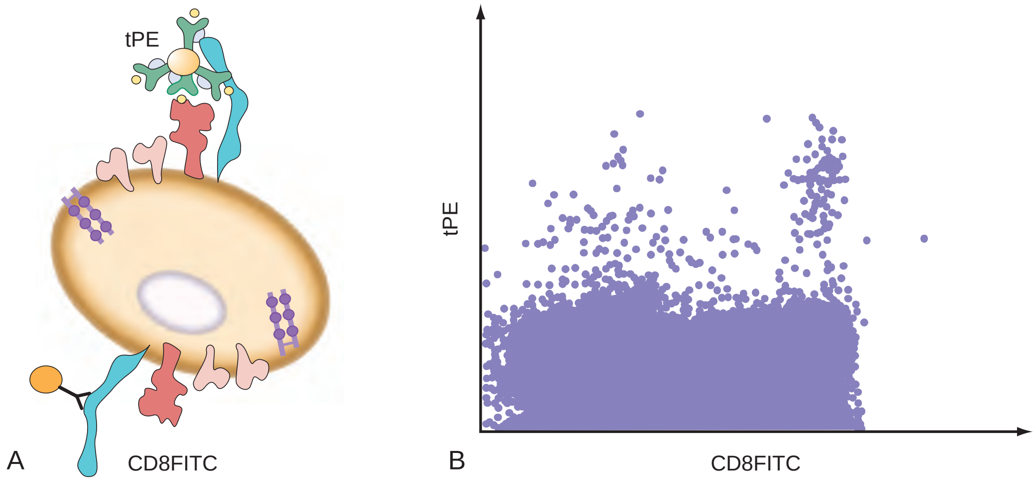

Figure 114.6 SCHEMATIC REPRESENTATION OF THE MECHANISM OF BINDING OF TETRAMERIC PEPTIDE/HUMAN LEUKOCYTE ANTIGEN COMPLEXES (THLA) TO ANTIGEN-SPECIFIC T CELLS. (A) Binding of tHLA to T-cell receptor. The tHLA consists of four HLA/peptide complexes identical to the ones recognized by the T cell on the surface of live cells. Each HLA molecule is modified to contain one biotin molecule that serves as a bridge for binding to tetravalent streptavidin molecules fluorescently labeled. (B) Actual fluorescence-activated cell sorter (FACS) analysis result of CD8$^+$, tHLA-positive T cells. *(Modified from Monsurro V, Nargosen D. Immunotracking of specific cancer vaccine CD8$^+$ lymphocytes, ASHI Q. 2003;26:100.)*

GVN. The understanding of action mechanisms in various nonclassic HLA genes as well as KIR has opened a new field. The study examining the function of the innate immune response in the context of transplantation and other immunopathologies is a result of this. Together with HLA, immunogenetics is rapidly growing, driven by the realization that polymorphism is the hallmark of human immunopathology as its spans mHag, KIR, cytokines, and their receptors. Each of these is interwoven in an intricate array of interdependent functions that cannot be discounted. Modern methods should be able to adopt high-throughput systems for the parallel assessment of all of these variables when addressing the genetic makeup of an individual in correlation with the natural or therapeutic history of his or her disease. The comparison of donor and recipient protein profiling and cytokine polymorphism may offer insights into the rejection mechanism when matched donor grafts are used. Finally, the increased use of T-cell-directed immunization is driving renewed interest in high-resolution typing of HLA molecules to allow a more accurate interpretation of clinical and immunologic results. In the coming years, there will be an abundance of data generated from various methods for next generation sequencing. Utilization of this data will have tremendous impact on understanding the clinical and immunological implications in regard to HLA. This data will require an enormous effort with bioinformatics at the forefront.

HUMAN NEUTROPHIL ANTIGENS AND THEIR CLINICAL SIGNIFICANCE

Lalezari et al. described the first granulocyte antigens. These antigens were designated *N* for neutrophil. Each antigen system was described alphabetically, and each allele was described numerically in order of discovery. They identified NA1 in 1966 and its allele, NA2, in 1972.[212,213] In 1971, Lalezari et al.[213] described another granulocyte antigen, NB1. Reports of several other granulocyte antigens followed.

A new nomenclature was established in 1998 by the International Society of Blood Transfusion Working Party (Table 114.4).[214] In this nomenclature, antigen systems are referred to as *human neutrophil antigens*, or HNA. The antigen systems—that is, the polymorphic forms of the immunogenic proteins—are indicated by integers, and specific antigens within each system are designated alphabetically by date of publication. Alleles of the coding genes are named according to the Guidelines for Human Gene Nomenclature. Neutrophil antigens NA1 and NA2 became HNA-1a and HNA-1b, and NB1 became HNA-2. The serology, biochemistry, molecular biology, and clinical significance of these antigens are reviewed here.

THE HNA-1 ANTIGEN SYSTEM

Expression of HNA-1 Antigens

HNA-1 antigens are expressed only on neutrophils. HNA-1 antigens are located on the low-affinity Fc-γ receptor IIIb (FcγRIIIb), CD16.[215–218] FcγRIIIb, HNA-1a, HNA-1b, HNA-1c, and HNA-1d antigens are expressed on all segmented neutrophils, approximately one-half of neutrophilic metamyelocytes, and approximately 10% of neutrophilic myelocytes.[219] Neutrophil expression of FcγRIIIb and HNA-1 antigens are diminished by the treatment of neutrophils with stimulants such as complement component C5a and chemotaxin F-met-leu-phe or granulocyte colony-stimulating factor (G-CSF). Soluble Fc γ RIIIb is present in plasma, and it has the same HNA-1 polymorphisms found on neutrophils. Fc γ RIIIb released from granulocytes is the source of the soluble Fc γ RIIIb and HNA-1 antigens.[220]

Biochemistry

Fc γ RIIIb is a glycoprotein with 233 amino acids and is glycosylphosphatidylinositol (GPI) anchored.[215–218] Its molecular weight is 50 to 80 kDa, and the glycoprotein has *N*-linked carbohydrate side chains. HNA-1a form of Fc γ RIIIb is 50 to 65 kDa, the HNA-1b form of Fc γ RIIIb is 65 to 80 kDa, and the heterozygous form is 50 to 80 kDa. Differences in *N*-glycosylation account for the differences in molecular mass.

Molecular Biology

Fc γ RIIIb and the HNA-1 antigens are encoded by the FCGR3B gene located on chromosome 1q23–24 within a cluster of two families of Fc γ R genes, FCGR2 and FCGR3. The FCGR3 family is made up of FCGR3A and FCGR3B. FCGR3B is highly homologous to FCGR3A, which encodes Fc γ RIIIa. Only four nucleotides differ between FCGR3B and FCGR3A (Table 114.5). The most important difference between the two genes is a C to T change at 733 in FCGR3B that creates a stop codon. As a result, FCGR3A has 21 more amino acids than FCGR3B, and FCGR3A is a transmembrane rather than GPI-anchored glycoprotein. Fc γ RIIIa is not recognized by antibodies specific to HNA-1 antigens, but the similarities between FCGR3A and FCGR3B complicate genotyping of HNA-1 alleles.

HNA-1a, -1b, -1c and -1d Polymorphisms

The neutrophil-specific HNA-1 antigen system is made up of four alleles: HNA-1a, -1b, -1c and -1d (see Table 114.4).[221] The gene frequencies of the alleles vary widely among different racial groups. Among Whites of European descent, the frequency of the gene encoding HNA-1a, FCGR3B*01, is between 0.30 and 0.37, and the frequency of the gene encoding HNA-1b, FCGR3B*02, is between 0.63 and 0.70.[222–226] In Japanese and Chinese populations, the FCGR3B*01 gene frequency is between 0.60 and 0.66, and the FCGR3B*02 gene frequency is between 0.30 and 0.33.[215,216,219,223–226] The gene frequency of the gene encoding HNA-1c, FCGR3B*03, also varies among racial groups. FCGR3B*03 is expressed by neutrophils in 4% to 5% of Whites and 25% to 38% of African Americans.[227]

The FCGR3B*01 gene differs from the FCGR3B*02 gene by only five nucleotides in the coding region, at positions 141, 147, 227, 277, and 349 (see Table 114.5).[215–218] Four of the nucleotide changes result in changes in the amino acid sequence between the HNA-1a and HNA-1b forms of the glycoprotein. The fifth polymorphism at 147 is silent. The glycosylation pattern of the protein differs between the two antigens because of two nucleotide changes at bases 227 and 277. The HNA-1b form has six *N*-linked glycosylation sites, and the HNA-1a form has four glycosylation sites.

TABLE 114.4 International Society of Blood Transfusion Nomenclature

Antigen System	Antigens	Location	Former Name	Alleles
HNA-1	HNA-1a	FcγRIIIb, CD16	NA1	FCGR3B*01
	HNA-1b	FcγRIIIb, CD16	NA2	FCGR3B*02
	HNA-1c	FcγRIIIb, CD16	SH	FCGR3B*03
	HNA-1d	FcγRIIIb, CD16		FCGR3B*02
HNA-2	HNA-2	CD177 (NB1 gp)	NB1	CD177
HNA-3	HNA-3a	CTL-2	5b	SLC44A2*01
HNA-4	HNA-4a	CD11b (CR3)	Mart(a)	ITGAM*01
HNA-5	HNA-5a	CD11a (LFA-1)	Ond(a)	ITGAL*01

CR3, C3bi receptor; *gp*, glycoprotein; *HNA*, human neutrophil antigen; *LFA-1*, leukocyte function–associated antigen-1.

The gene encoding the HNA-1c form of Fc γ RIIIb, FCGR3B*03, is identical to FCGR3B*02 except for a C to A substitution at nucleotide 266, resulting in an alanine to aspartate change at amino acid 78 of Fc γ RIIIb (see Table 114.5).[221] In many cases, FCGR3B*03 exists on the same chromosome with a second or duplicate FCGR3B gene.[221,228]

Antibodies to HNA-1d have recently been described in two cases of neonatal immune neutropenia. The antigen HNA-1d is also encoded by FCGRB*02.[229]

FC γ RIIIB Deficiency

Blood cells from patients with paroxysmal nocturnal hemoglobinuria lack the GPI-linked glycoproteins, and their granulocytes express reduced amounts of Fc γ RIIIb and the HNA-1 antigens.[218] Genetic deficiencies of granulocyte Fc γ RIIIb and HNA-1 antigens have also been reported. With inherited deficiency of Fc γ RIIIb, the FCGR3B gene is deleted along with an adjacent gene, FCGR2C.[222,230] Among White subjects, the incidence of individuals homozygous for FCGR3B deletion is about 0.1%.[231,232] However, among Africans and African Americans, the incidence is much higher; in one study, 3 of 126 Africans were found to be FCGR3B-deficient,[227] and in another, 1 of 53 was found to be FCGR3B-deficient.[225]

Function of HNA-1 Antigens

The low-affinity Fc-γ receptors link humoral immunity to cellular immune function; specifically, Fc γ Rs on effector cells recognize cytotoxic IgG molecules and immune complexes containing IgG molecules. Polymorphisms in Fc γ RIIIb affect neutrophil function. Neutrophils that are homozygous for HNA-1b have a lower affinity for IgG3 than granulocytes homozygous for HNA-1a.[233] Neutrophils from people who are homozygous for HNA-1b phagocytize erythrocytes sensitized with IgG1 and IgG3 anti-Rh monoclonal antibodies and bacteria opsonized with IgG1 at a lower level than granulocytes homozygous for HNA-1a.[234,235]

The Clinical Relevance of FC γ RIIIB Deficiency

Despite the important role of Fc γ RIIIb in neutrophil function, deletion of the entire Fc γ RIIIB gene does not cause major clinical problems, and most people with Fc γ RIIIb deficiency are healthy. However, too few patients have been studied to identify a slight increase in susceptibility to infection or autoimmune disease due to Fc γ RIIIb deficiency.

THE HNA-2 ANTIGEN SYSTEM

HNA-2 is an isoantigen without allelic variation. It was previously known as NB1.[236] Monoclonal antibodies specific to HNA-2 have been clustered as CD177.

TABLE 114.5 Nucleotide Differences Among the Genes Encoding the HNA-1a, HNA-1b, and HNA-1c Antigens of Fcγ RIIIb Base Pair Position

Gene	141	147	227	266	277	349	473	505	559	641	733
FCGR3B*01	AGG	CTC	AAC	GCT	GAC	GTC	GAC	CAC	GTT	TCT	TGA[a]
FCGR3B*02	AGC	CTT	AGC	GCT	AAC	ATC	GAC	CAC	GTT	TCT	TGA[a]
FCGR3B*03	AGC	CTT	AGC	GAT	AAC	ATC	GAC	CAC	GTT	TCT	TGA[a]
FCGR3A	AGG	CTC	AGC	GCT	GAC	ATC	GGC	TAC	TTT	TTT	CGA

Note: Differences among genes are in bold.
HNA, Human neutrophil antigen.
*N-Glycosylation site.
[a] Stop codon.

Expression of HNA-2

HNA-2 is is expressed only on neutrophils, neutrophilic metamyelocytes, and myelocytes.[219,237] HNA-2 is unique in that it is expressed on subpopulations of neutrophils. The mean size of the HNA-2–positive subpopulation of neutrophils is 45% to 65%.[238–240] The expression of HNA-2 is greater on neutrophils in women.[239,241] The size of the HNA-2–positive subpopulation of neutrophils in women is approximately 60%, compared with approximately 50% for men. Neutrophil expression of HNA-2 is greater in pregnant women than in healthy female blood donors.[241] The surface expression of HNA-2 is slightly upregulated by treatment with the chemotactic peptide F-met-leu-phe.[238] The administration of G-CSF to healthy subjects for several days increases the proportion of neutrophils expressing HNA-2 to near 90%.[242]

CD177 Glycoprotein Biochemistry

The glycoprotein carrying HNA-2a, CD177, was previously known as the NB1 glycoprotein. It is located on neutrophil plasma membranes and secondary granules[238,243] and is linked to the plasma membrane via a GPI anchor.[238] Although some GPI-anchored proteins are shed by F-met-leu-phe–treated neutrophils, CD177 is not, nor is soluble CD177 glycoprotein present in plasma.[238] The molecular weight of CD177 is 58 to 64 kDa, and it contains *N*-linked carbohydrate side chains.[238,243]

Molecular Biology

The gene encoding CD177 is located on chromosome 19q13.31, and its coding region consists of 1311 bp that code for a protein of 416 and a signal peptide of 21 amino acids.[244,245] The predicted protein has two cysteine-rich domains, three potential *N*-linked glycosylation sites, and a potential ω-site for attachment of the GPI anchor.[245] This gene belongs to the Ly-6 snake toxin superfamily. Other genes in this family include urokinase-type plasminogen activator receptor (uPAR) (CD87) and decay-accelerating factor (CD59).

Polymorphisms

HNA-2 is expressed on neutrophils by approximately 97% of persons of European origin, 95% of African Americans, and 89% to 99% of Japanese.[239,246–248] A HNA-2 negative neutrophil phenotype is caused by a CD177 transcription defect that is not completely understood.[249,250] The most common cause is an A to T change at position 787 that results in a premature stop codon within exon 7. Heterozygosity for 787 A and 787 T has been associated with reduced expression of HNA-2.[250]

Clinical Relevance of HNA-2 Antigens

The rare women who produce HNA-2–specific alloantibodies and who lack NB1 glycoprotein are healthy. The expression of HNA-2 is reduced on neutrophils from people with paroxysmal nocturnal hemoglobinuria and chronic myelogenous leukemia,[237] but it is unknown whether this has any clinical significance. CD177 mRNA is overexpressed by neutrophils from patients with polycythemia rubra vera and essential thrombocytosis.[251,252] The role of CD177 in neutrophil function is unknown. In some studies, HNA-2 may have a role in the adhesion of neutrophils to endothelial cells.[253]

THE HNA-3 ANTIGEN SYSTEM

The HNA-3 antigen system has one antigen, HNA-3a, which was previously known as 5b. HNA-3a is expressed by neutrophils, lymphocytes, platelets, endothelial cells, and kidney, spleen, and placental cells. HNA-3a has a gene frequency of 0.66.[254] HNA-3a is located on the choline transport-like protein-2 (CTL-2) and is encoded by SLC44A2. The HNA-3a phenotype is due to a nucleotide polymorphism that results in an arginine rather than a glutamine at position 152 of CTL-2.[250,255,256] Several cases of transfusion-related acute lung injury (TRALI) have been associated with transfusion of plasma containing anti-HNA-3a.[257,258]

HNA-4 AND HNA-5 ANTIGEN SYSTEMS

HNA-4 and HNA-5 antigens are located in the β_2-integrins. Each antigen system contains only a single antigen, HNA-4a and HNA-5a, respectively. The HNA-4a antigen was previously known as Mart(a). HNA-4a has a phenotype frequency of 99.1% in White individuals. HNA-4a has been located on the αM chain (CD11b) of the C3bi receptor (CR3) and is caused by a single nucleotide substitution of G to A at position 230 of the gene ITGAM.[250,259] The substitution would be predicted to result in an arginine-to-histidine polymorphism at amino acid 61.

A second polymorphism of the β_2-integrins, HNA-5a, was first described as Ond(a). HNA-5a was found to be expressed on the αL integrin unit, leukocyte function–associated antigen-1 (LFA-1) (CD11a) and is caused by a G to C single nucleotide substitution at position 2372 of the gene ITGAL. This change predicts an amino acid change of arginine to threonine at amino acid 766.[250,259]

CLINICAL SIGNIFICANCE OF ANTIBODIES TO NEUTROPHIL ANTIGENS

Alloimmune Neonatal Neutropenia

During pregnancy, mothers can become alloimmunized to neutrophil antigens. Maternal IgG directed to neutrophils can cross the placenta and destroy the neonate's neutrophils. Maternal alloimmunization to neutrophil antigens can occur in utero and affect the first child. Most neonates experience isolated neutropenia, but the cytopenias are self-limiting and resolve as the antibody is cleared. The alloimmunized mothers produce and carry the antibodies, but the antibodies do not react with the mother's blood cells or tissues, and they have normal neutrophil counts. Antibodies to neutrophil-specific antigens HNA-1a, HNA-1b, and HNA-2 most commonly cause neonatal alloimmune neutropenia (Table 114.6).[254,260] Antibodies to HNA-1c, HNA-3a, and HNA-3b rarely cause alloimmune neonatal neutropenia.[261] Mothers with FcγRIIIb deficiency have produced FcγRIIIb-specific antibodies that caused neonatal neutropenia.[231,254,260]

Newborns with alloimmune neutropenia are usually asymptomatic. Most often, the neutropenia is detected in the first week of life when the neonate becomes febrile or develops an infection and a neutrophil count is done. Typically, the counts are 0.100 to 0.200 × 10^9/L. Some neonates have normal neutrophil counts the first day of life, but they become neutropenic on their second day.[260] White blood cell count, platelet count, and hemoglobin level are usually normal, but eosinophilia or monocytosis may be present. If a bone marrow biopsy is performed, it often shows normal numbers of erythroid progenitors and megakaryocytes with hyperplasia of myeloid progenitors.

The clinical course is quite variable. An occasional infant is asymptomatic, but almost all affected children have an infection. The most common infections are umbilicus infections, skin infections, abscesses, and respiratory tract infections. Less commonly, infants experience otitis media, urinary tract infections, and gastroenteritis. Serious infections such as sepsis, pneumonia, and meningitis can occur. The duration of the neutropenia may be as short as a few days or as long as 28 weeks.[260] The mean duration of neutropenia is about 11 weeks.[260]

For an asymptomatic child, no immediate treatment may be required. Prompt and aggressive antibiotic treatment of children with fevers or other signs of infections is indicated. Intravenous

TABLE 114.6 Specificities of Antibodies in Alloimmune Neonatal Neutropenia

Antigen	$N = 18$[211]	$N = 48$[253]
HNA-1a	28%	10%
HNA-1b	22%	8%
FcγRIIIb	0%	8%
HNA-2a	11%	2%
HNA-3a	0%	2%
Unknown	0%	15%
HLA class I[251]	11%	54%
Negative	28%	38%

HLA, Human leukocyte antigen; *HNA*, human neutrophil antigen.

immunoglobulin has a limited role in the treatment of neonatal alloimmune neutropenia. Approximately half the patients treated have a transient increase in count lasting only a few days. The use of G-CSF to treat alloimmune neutropenia has also had mixed results. The administration of G-CSF elevates the neutrophil count in some, but not all, neonates.[260]

AUTOIMMUNE NEUTROPENIA OF CHILDHOOD

Autoimmune neutropenia has been well described in children.[262–265] Typically the onset of the autoimmune neutropenia of children begins at 8 months of age, but children between 1 and 36 months of age can be affected. Most studies found that neutrophil counts recover spontaneously by the age of 5 years, with a median of 13 to 20 months of neutropenia.[262–265]

In most cases, children presented with severe neutropenia having neutrophil counts of less than 0.5×10^9/L. Monocytosis has been reported to occur in up to 38% of patients. Results of bone marrow biopsies in affected patients usually show normal to hypercellular marrow with a decreased number of mature granulocytes. Febrile episodes and infections, including bacterial skin infections, otitis media, respiratory tract infections, and urinary tract infections, are common. Life-threatening complications are rare.

Antibodies to neutrophils can be detected in up to 98% of affected patients. If an antibody specificity is identified, the antibodies are almost always specific to epitopes located on FcγRIIIb. The antibodies are directed to HNA-1a in 10% to 46% of patients, to HNA-1b in 2% to 3% of patients, and rarely to FcγRIIIb epitopes expressed by granulocytes from all donors.[262,265]

Autoimmune neutropenia has been treated with corticosteroids, intravenous immunoglobulin, and G-CSF. Approximately half the patients responded to intravenous immunoglobulin, but neutrophil counts remained elevated for only 1 week.[262] Almost all the patients responded to G-CSF and 75% to corticosteroids, and neutrophil counts remained elevated as long as the drugs were given.

TRANSFUSION REACTIONS

Antibodies to neutrophil and HLA antigens can cause febrile nonhemolytic transfusion reactions and TRALI. Before the widespread transfusion of leukocyte-reduced blood components, approximately 0.5% of transfusions were associated with febrile nonhemolytic transfusion reactions, and leukocyte antibodies are a common cause of these reactions. These febrile reactions are caused by the interaction of leukocyte antibodies in the transfusion recipient with leukocytes contained in the transfused blood components. These reactions can be prevented by the use of components that have been filtered to remove leukocytes.

A more serious type of transfusion reaction associated with leukocyte antibodies is the acute noncardiac pulmonary edema, or TRALI. This entity is characterized by acute respiratory distress that usually occurs within 4 hours after a transfusion. These reactions are characterized by dyspnea, hypoxia, and bilateral pulmonary infiltrates on chest radiograph without cardiomegaly or pulmonary vascular congestion. The mortality rate associated with TRALI is approximately 5%.[266] Of patients with TRALI, 80% have rapid resolution of pulmonary infiltrates and return of arterial blood gas values to normal within 96 hours after the initial respiratory insult. However, pulmonary infiltrates have persisted for at least 7 days after the transfusion reaction in 17% of TRALI patients.
